ABSTRACT

A building emulator can be used to test energy management and control systems (EMCS). The emulator uses a computer program to simulate the responses of a building including the equipment, building space, and building envelope to EMCS commands. Building model software for the emulator has been developed at the National Bureau of Standards (NBS) in an effort to assist the United States Naval Civil Engineering Laboratory (NCEL), which is developing a sophisticated building emulator.

The concept of the building emulator and the building emulator computer program are described in this report. The program includes the weather, the air handling unit, the zone, and the comfort model. In addition, the energy compilation routine is also included. The models presented here are simplified models. With these abridged models, a single zone building with exterior walls and a single deck air handling unit are simulated. A complete FORTRAN source code of the building emulator computer program is appended.

KEY WORDS: air handling unit simulation model; building emulator; building space zone model; computer simulation; EMCS algorithms; energy management and control systems (EMCS); HVAC emulator; local equipment simulation model; testing EMCS algorithms.

ACKNOWLEDGEMENT

The authors are indebted to the Naval Civil Engineering Laboratory, Department of Defense, and the Building Systems Division, Department of Energy, for funding this project.

1. INTRODUCTION

Advances in computer and communications technology have made feasible the use of computers for controlling the heating, ventilation, and air conditioning (HVAC) systems of buildings. Such control systems are usually called energy management and control systems (EMCS). As for any building equipment, it is desirable to have standard testing and rating methods for EMCS. One benefit of such standards is that a more intelligent choice of an EMCS for a building can be made if systems from several manufacturers are tested using standard methods. Once an EMCS is installed, acceptance testing of the system is possible by comparing field test results to design specifications.

1.1 The Concept of a Building Emulator

One approach to testing of EMCS systems is the use of a building emulator. A building emulator is a special computer connected to the sensor inputs and command outputs of an EMCS. No actual HVAC equipment or building is connected to the EMCS. The emulator uses a computer program to simulate the responses of a building (including the equipment, building space, and building envelope) to EMCS commands. The EMCS then controls this simulated building as if it were an actual one. The advantages of using an emulator are that an EMCS may be tested with any type of building if a model is available, and tests can be repeated on different EMCS under the same conditions. Although experience with emulators is limited, it appears that the emulator testing approach is the most desirable in terms of the cost of testing, reproducibility of results, and control of test conditions.

A building emulator can be used to test EMCS algorithms, which may be defined as the software programs in the EMCS which use the EMCS sensors to collect information, make decisions based on current and past information and parameters, and make changes to the building through the EMCS actuators. EMCS algorithms can either be direct digital control (DDC) to control valves and dampers directly, for example, or supervisory to determine start/stop times and setpoints, for example. If a building emulator is used to test EMCS algorithms, it is not necessary to know the exact structure of the algorithm software. Since EMCS software is often proprietary, this is a definite advantage.

Before a building emulator can be used, it must be possible to connect an emulator to an EMCS to be tested. The recommended approach is the connection of the emulator to the EMCS in place of the regular EMCS sensors and actuators. Since it is likely that the EMCS sensors are electrical in nature, they can be replaced with voltage or current sources under the control of the emulator. The EMCS will be unable to distinguish between an actual sensor producing an electrical signal and the emulator producing the same electrical signal. This method allows the EMCS algorithm to be tested directly without the effects of sensors. This implies that a building emulator cannot be used

to test the instrumentation on an EMCS since no sensors or actuators are involved.

1.2 Existing and Planned Building Emulators

Two building emulator prototypes have been built in order to demonstrate the concept of EMCS testing using an emulator. At the United States National Bureau of Standards (NBS), a simple building emulator was constructed in 1983. This emulator demonstrated the basic concept of a building emulator but was not transportable, was limited in capacity, and had a model which was too simple for quantitative algorithm testing.

A second example of a prototype emulator was developed by a contractor for the United States Naval Civil Engineering Laboratory (NCEL) in 1983 [Wise (1984)]. This device, which was referred to as an EMCS exerciser, was designed to be transportable and was used in field tests of actual EMCS installations. Complex software in the exerciser allowed an operator to easily prepare for and run tests. The tests were intended to determine if EMCS supervisory algorithms were operating properly. The exerciser produced reports of the time of occurrence and nature of all EMCS actions during the test. These reports were compared to reports from the EMCS to determine if any problems existed. The unit was not designed to allow a quantitative testing of algorithms, only to determine if the algorithms were operating and controlling the correct command outputs. The exerciser did work as designed and was capable of revealing areas requiring attention in real EMCS installations.

NCEL, with the assistance of NBS, is currently developing a building emulator of greater sophistication than the examples given above. This emulator will have the field transport and general connection features of the NCEL exerciser plus a detailed building simulation model and improved control and evaluation software. NBS is responsible for developing the building model to be used in the NCEL emulator. This report is intended to describe the building model software which has been developed by NBS. The NBS building model does not simulate a complete building, but simulates a single building zone with exterior walls and an air handling unit.

The NCEL/NBS emulator will be used for either factory or field acceptance tests of EMCS algorithms. A factory test will be performed at an EMCS manufacturer facility to determine the capabilities of algorithms on a specific EMCS. A field acceptance test will be used to determine whether an EMCS installed at a specific site is operating in accordance with design specifications. The initial version of the emulator will be designed to test supervisory EMCS algorithms and will not test DDC algorithms.

1.3 Testing of EMCS Algorithms with the NCEL/NBS Building Emulator

Eight types of supervisory control algorithms have been selected for testing

with the NCEL/NBS building emulator. The concepts of the algorithms will not be discussed in this report. Discussion of these EMCS algorithms may be found in other reports [May (1983), Park (1983), Park, Kelly, Kao (1984), Park (1984), and May (1984)]. The types of algorithms to be tested are listed below:

1. Scheduled Start/Stop
2. Duty Cycling
3. Demand Limiting
4. Optimum Start/Stop
5. Day/night Setback
6. Economizer
7. Ventilation/Recirculation
8. Air Setpoint Reset

The emulator model described in this report will not currently support the testing of the demand limiting algorithm. A model of electrical demand in a building would have to be added to the emulator simulation software.

The test procedure to be used for testing EMCS algorithms will determine the exact characteristics that the NCEL building emulator will have. The final form of the test procedure is not known as of the writing of this report. The test procedure cannot be determined entirely by objective means and must result from negotiations between building owners, equipment manufacturers, testing personnel, and standards organizations. For the NCEL emulator it will be assumed that the test procedure will be based on the concept of testing of computers using a 'benchmark' computer program which exercises various operations of any computer on which it is run. Like a program which runs at different speeds depending on the computer on which it is executing, an EMCS algorithm will behave differently depending on the building and climate where it is tested. If 'benchmark' or 'reference' buildings are used for a building emulator, then results of testing different algorithms of the same type on these buildings may be compared.

The building simulation program in the emulator will simulate the response of a building to EMCS control actions. The emulator will be used to provide reproducible predictions of energy use and temperature levels for a set of hypothetical 'reference' buildings which are being controlled by the EMCS system under test.

1.4 Software Components of the NCEL/NBS Building Emulator

The NCEL/NBS emulator computer will employ a multi-tasking disc operating system which will allow several software tasks or processes to effectively appear to be running concurrently. When the emulator is being used to test an EMCS algorithm, there will be two important processes running. One of these is the building simulation program which is described in this report. The other process is an input/output (I/O) program which will read from and write to the

hardware connected to the EMCS sensors and actuators. These two processes will have a common data area in computer memory that both may read from and write to.

If the EMCS sends a command by changing the state or signal level of an EMCS command output, the I/O program detects this and changes the data area that the simulation program uses for command input variables such as start/stop fan, or supply air setpoint. Based on the input variables and model parameters, the simulation program predicts values for variables such as temperatures in the building and HVAC equipment and status points. The simulation program places these values in the common memory area. The I/O program reads these values from the common area and sets the signal levels on the EMCS sensor inputs.

In addition to the model and I/O software, the NCEL emulator will have control software. An operator control program will be used to start and stop the simulation and I/O programs, select parameter files to be used, and determine duration of testing. At the end of tests the simulation program will deposit accumulated energy use by the emulated building into data files. Evaluation software will be used to examine test results and produce evaluations of specific EMCS algorithms such as scheduled start/stop, demand limiting, or setpoint reset.

The next section of this report describes the model software for the emulator in detail. No additional information will be given on the other software components of the emulator since these were not developed at the time this report was written.

2. BUILDING SIMULATION COMPUTER PROGRAM

The building emulator model computer program that was completed by NBS was designed to simulate any type of HVAC system and all possible modes of heat transfer in a zone. However, not all subroutines were completed in order to create a more simplified version. This simplified version will be termed the abridged version. The extent of simplifications will be noted in the sections following.

The building emulator building simulation computer program was written completely in the high level computer language FORTRAN 77 and is appended in the APPENDIX. This section will describe the actual computer program that was developed but will not present the specific equations used to model the building. The emphasis in this chapter will be on describing the data structures, data interface, programming logic and component parts of the program. Following chapters will present detailed equations for the component models of the simulation program.

2.1 Data Structures and Interface to Building Emulator

The building emulator model program is connected to the other programs in the emulator by three data paths. These are the common data area, parameter input files, and report output files. In terms of the building model, the parameter input files control duration of the simulation, timestep, initial conditions, and configure the building systems to be simulated. The report files are the program output, and the common data area represents the state of the simulation and allows input of time dependent boundary conditions.

The common data area is implemented in the emulator model program as a FORTRAN common block. Within the model program, this common block is given the name STATE1 and contains 100 real variables and 100 logical variables. The common block STATE1 contains the 'state vector' for the model. This means that at any time, the values of the variables in STATE1 describe the state of the simulation. Tables 2-1 through 2-4 list all of the variables in the state vector and the engineering units used. The number on the left is the position of the variable in the state vector array. Not all of the state vector positions are used to allow for any future expansion of the model. The variables in table 2-1 are all set by the emulator model program. Selected values in the common area will be converted to electrical signals on the EMCS inputs.

The variables listed in table 2-2 are energy variables which contain cumulative energy used by the building in various categories. This information is written to report files at the end of an emulator test run. More information on energy variables is given in section 7.

Table 2-3 lists variables which the emulator model program uses as input (independent variables). The values of these variables in the common area are set depending on what commands have been received from the EMCS. Some of the variables are logical and some are real variables. The logical variables have two states for use in controlling a two-state device such as a fan. The real variables are used to determine values such as setpoints.

The variables in table 2-4 are set by the emulator program but are not converted to signals for the EMCS. These are comfort variables which are written to a report file at the end of a test period.

The input parameter files are read by the emulator model program during the initialization of the program. These files are described in section 2.3. The input parameters files are either model parameter files or test control parameter files.

2.2 General Program Organization and Control

The emulator building model computer program is written in the form of a FORTRAN subroutine which can be called from the main program section of the emulator model process running in a multi-tasking system (see section 1.4). The main logic diagram for the emulator model is shown in figure 2-1. It is assumed that the emulator subroutine is called repeatedly without any time delays between calls.

Table 2-2. Emulator model state variables - Energy variables

The emulator program consists of three parts. These are the model equations section, the control section, and the initialization section. During the initialization of the program, a simulation time step, for example thirty seconds, is selected. In a conventional simulation, the control section of the program would advance the variables which contain the time of day and cause the model equations to be solved. The conventional simulation will execute at the full speed of the computer. For an emulator, however, the simulation is artificially slowed so that the time intervals as measured by a real time clock between solutions of the model correspond to the value of the simulation time step. The control software for an emulator must obtain the current time of day from a real-time clock in the computer and only allow the model equations to be solved when a real amount of time has passed.

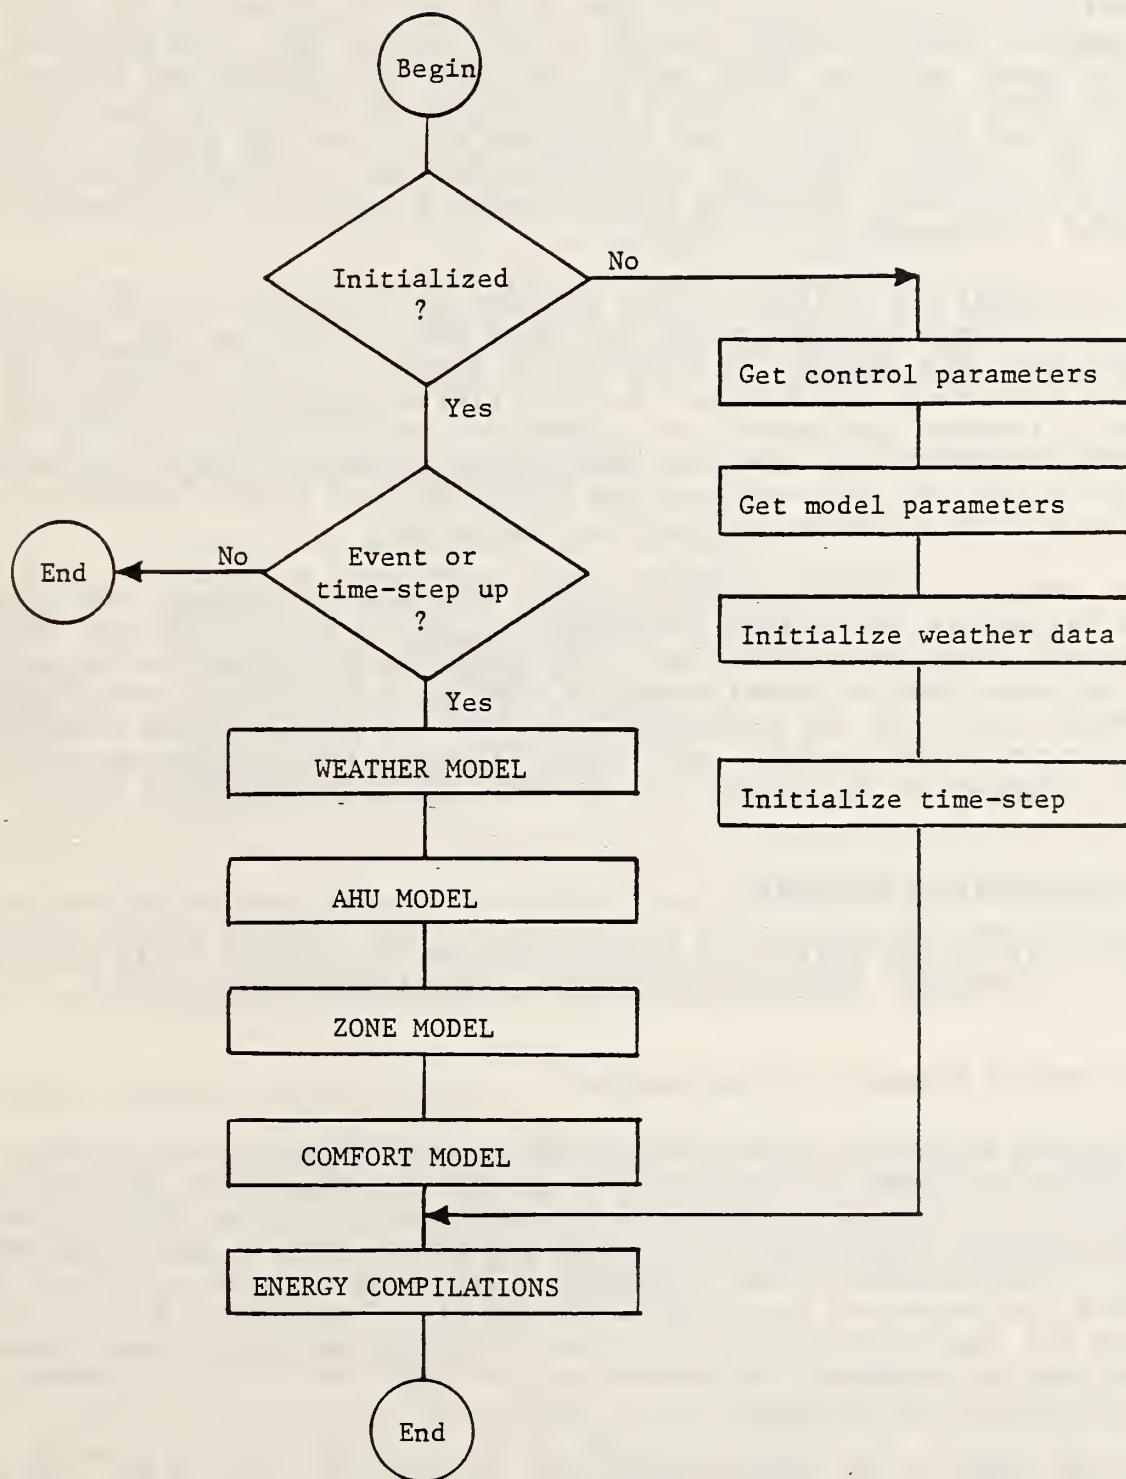

Figure 2-1. Logic diagram of the emulator model program

In addition to monitoring a real-time clock for the passage of the time-step, the emulator building model program control section must also determine if a command event has taken place before the time-step interval has elapsed. If a command event occurs, the program must temporarily adjust the time step to be equal to the time interval that has passed since the most recent solution of the model equations and cause the model equations to be solved immediately. If this is not done, there may be unacceptable delays in the response of the emulator to commands from the EMCS.

Each time that the emulator model subroutine is called, a determination is made as to whether initialization has taken place. If it has not, the program initializes. This process is described in section 2.3. If initialization has already occurred, the program control section determines if either the timestep interval has passed, or a command event has taken place. If neither of these conditions has occurred, then the subroutine is exited. If either of the conditions has occurred, then the model equations section causes the model equations to be solved for the current time of day.

After either initialization or model equations solution, the program calls the energy compilation subroutine. If called after equations solution, the energy compilation subroutine determines the energy used by the emulated building since the last model equations solution and stores a cumulative total of energy used since the beginning of the emulator model program execution. If called after initialization, the cumulative energy totals are reset. After the energy compilation is finished, the emulator model subroutine is exited.

2.3 Initialization Routines

The initialization section of the emulator model program loads simulation control parameters, model parameters, and initializes time variables.

2.3.1 Control Parameter Initialization

The control parameter input subroutine, named CONPAR, is called during the initialization phase to load control parameters. The control parameters are previously stored in a file called the configuration file. CONPAR opens the configuration file and reads the control parameters from it. Table 2-5 shows a sample configuration file. All reading from the file is performed using FORTRAN list-directed read operations and therefore quotes must be placed around the character information, but otherwise no formatting or special delimiters are required. The entries on the right are strictly comments and are not read by the program.

The first entry in the configuration file is the start time of the test using the building emulator. In the example configuration file, this is 12:30. The next entry is the duration of the test in days, hours, minutes, and seconds. In table 2-5, the example test duration is one day and three hours, or a total

of 27 hours. The next four entries in the configuration file are the names of files containing the model parameters. The contents of these files are discussed in the following sections. The names of these files would normally be changed to select a different set of model parameters to allow a different building to be simulated, or the same building to be simulated in a different climate. The seventh entry in the configuration file is the name of the file used to initialize the state vector. The eighth configuration file entry is the weather 'season' to use for the simulation. This will be discussed more fully in section 2.3.2.5. The last entry in the configuration file is the simulation time-step. The time-step is discussed in section 2.2 and section 2.4. The smaller the timestep, the greater the accuracy of the results, but the program execution time rises quickly with decreasing time step. A larger timestep decreases execution time up to a point. Beyond this point the execution time does not change.

Table 2-5. Sample simulation configuration file

12 30 0	'start time: hours, minutes, seconds'
1 3 0 0	'execution time: days, hours, minutes, seconds'
'HVAC.PAR'	'BUILDING HVAC SYSTEM PARAMETER FILE'
'USE.PAR'	'BUILDING USE PARAMETER FILE'
'CLIMATE.PAR'	'WEATHER DATA PARAMETER FILE'
'SHELL.PAR'	'BUILDING SHELL PARAMETER FILE'
'WINTER.INI'	'STATE VECTOR INITIALIZATION FILE'
'WINTER	'SEASON TO USE FOR EMULATION'
20	'Timestep IN SECONDS'

After the control parameters have been read, the CONPAR subroutine calculates the absolute ending time for the emulator test run by adding the test duration to the start time. The ending time is used to determine when to halt the execution of the emulator model program and write the report files.

2.3.2 Model Parameter Initialization

After the control parameters are initialized, the initialization section of the emulator model program calls the subroutine named PARAMA. This subroutine is used to initialize all model parameters. The model parameters are stored in several FORTRAN common blocks which are installed in the PARAMA subroutine and in the various model equation solution subroutines.

2.3.2.1 State Vector Initialization

The first function performed by the PARAMA subroutine is the initialization of the state vector. The variables in the building emulator simulation are located in a large array in a FORTRAN common block. This state vector contains 100 real variables and 100 logical variables. During the solution of the model equations, some of the state variables are calculated completely from the

current values of other variables and do not need to be initialized. Other state variables are calculated from the previous value of the state variable one time step back as well as from the current value of other variables. This latter type of variable must be given an initial value. The state vector variables are initialized using values read from the state vector initialization file. Table 2-6 shows a sample initialization file.

Table 2-6. Sample state vector initialization file

06	52.0	'TEMPERATURE of zone air (F)'
07	0.008	'HUMIDITY RATIO of zone air (lbw/lbda)'
08	21.0	'TEMPERATURE of zone wall interior (F)'
09	48.0	'TEMPERATURE of Zone wall surface (F)'
10	73.0	'TEMPERATURE of zone glass (F)'
80	81.0	'CONTROL POINT ADJUSTMENT supply air temperature (F)'
81	55.0	'CONTROL POINT ADJUSTMENT zone temperature (F)'
83	50.0	'CONTROL POINT ADJUSTMENT supply air RH (%)
92	200.0	'COMFORT minimum dry bulb temperature (F)'
01	.FALSE.	'COMMAND air handling unit on/off'
02	.FALSE.	'COMMAND economizer on/off'
03	.FALSE.	'COMMAND ventilation on/off'
04	.FALSE.	'COMMAND zone setback on/off'
10	.FALSE.	'STATUS air handling unit on/off'

There are three entries on each line of the initialization file. The first entry on the line is the position in the state vector to be initialized. This is a number from 1 to 100. It is assumed that the real numbers are initialized first. The lines in the file must have state vector position numbers in ascending numerical order. When a position number for a line is lower than the number in the preceding line, it is assumed that the following lines will now be used to initialize logical variables.

The second entry on the lines in the initialization file is the initial value to be assigned to the state vector variable. This is a real number constant for the real state variables and a logical constant for the logical state variables. The third entry on the initialization file lines is a comment identifying the name of the state variable. This is not read by the program.

2.3.2.2 Building Use Parameter Initialization

The second function performed by the PARAMA subroutine is the initialization of building use parameters. The building use parameter file contains information on the occupancy and equipment operating times for the building. An example of a building use parameter file is listed in table 2-7.

In the building use parameter file each line is used to determine a change in

the usage status of the building. Between the times indicated by the entries, the usage status is assumed to remain the same. The first column indicates the time in decimal hours that the change in building usage is to occur. The second column indicates the level of lighting in the space in watts. The third column determines the type of lighting used in the building. 'F' indicates fluorescent, and 'I' indicates incandescent. The fourth column is the power used by equipment in the zone in watts. The fifth column is the ratio of radiated energy to total energy for the equipment. The sixth column is the zone moisture gain rate due to the equipment in pounds of water per hour. The last five columns are counts of the number of occupants in one of five activity levels with Activity 5 being the most active. The activity levels are described in section 5.4.5.2.

Table 2-7. Sample building use parameter file

HRS	LIGHT(W)	TYPE	EQUIP	SENS(W)	EQUIP,LAT(LB/H)	ACT 1	ACT2	ACT3	ACT4	ACT5
0.0	100.	'F'	0.	0.5	0.	0	0	0	0	0
8.0	500.	'F'	200.	0.5	0.25	16	8	4	0	0
17.0	100.	'F'	0.	0.5	0.	0	0	0	0	0

After the parameters have been read from the file. The PARAMA subroutine performs some simplifying calculations. The purpose of the calculations is to determine the sensible heat gain rate from equipment, the sensible heat gain rate from people, the moisture gain rate from equipment, and the moisture gain rate from people for each usage state. The equations used are described in section 5.4.5.2. The calculated building use parameters are stored in the common block USE in five arrays. The five arrays contain the above calculated parameters and the time of occurrence for each usage state. A parameter in the program determines the maximum number of usage states.

2.3.2.3 Building Shell Parameter Initialization

After initializing the building use parameters, the PARAMA subroutine initializes the building shell parameters. The building shell parameter file contains parameters which describe the characteristics of the zone, zone walls, and zone windows, for the building to be emulated. Parameters describing the thermal capacity and insulation value of the zone enclosure are in this file. Also in the file are parameters for air infiltration and moisture absorption. An example of the contents of the file is given in table 2-8. The meaning of the entries is assumed to be explained by the comments on each line and will not be discussed here. Only the first value on each line is read by the program. No additional calculations are performed on the building shell parameters in subroutine PARAMA. The parameters are stored in a FORTRAN common block with the name SHELL.

2.3.2.4 HVAC System Parameter Initialization

After initializing the building shell parameters, the PARAMA subroutine initializes the building HVAC system parameters. The HVAC System parameter file contains a description of the heating and cooling equipment available in the building to be emulated. An example of this parameter file is given in table 2-9. The meaning of the entries is assumed to be explained by the comments on each line. Only the first value on each line is read by the program.

2.3.2.5 Climate Parameter Initialization

After initializing the building HVAC system parameters, the PARAMA subroutine initializes the building climate parameters. The building climate parameter file contains the parameters used to simulate the weather to which the emulated building is exposed. The information in the file is for a representative day at five different times of the year for a particular climatic area. These times of the year are termed 'seasons' and correspond to winter, late winter, spring, early summer, and summer. During any particular test, parameters for one season, which is selected by an entry in the emulator model configuration file, will be used to generate a one day variation in weather conditions. This day of weather will be repeated for any other days that the test is run. An example climate file is given in table 2-10. The first line in the file identifies the climate description. This is followed by the five groupings of parameters for five seasons. The season title is the first season information entry. The other entries are explained by the adjacent comments. Additional information about these parameters is given in chapter 3.

2.4 Simulation Control Routines

The simulation control section of the program is found in a subroutine given the name ECTROL. ECTROL has two output arguments, TIMEST and GO. TIMEST is an integer variable which returns the current time step for the simulation to use. GO is a logical variable which is returned as true if the model equations should be solved and false if the equations should not yet be solved.

ECTROL uses two subroutines, TIMINC and NUSTEP, to determine values for variables TIMEST and GO. TIMINC has two logical output arguments, STEPDN and TIMEUP. If a time interval equal to the simulation time step has elapsed since the last solution of the model equations, STEPDN is set true, otherwise it is set false. If the duration of the emulator test specified in the emulator configuration file has elapsed, TIMEUP is set true, otherwise it is set false. If TIMEUP is true, ECTROL calls REPORT, which generates the emulator model report files. EVENT is a global logical variable which is true if the command inputs in the state vector have changed since the last model equations solution, or false otherwise. If either EVENT or STEPDN is true, GO is set to TRUE and ECTROL calls NUSTEP. NUSTEP returns in the variable TIMEST the time elapsed since the last solution of the model equations.

2.5 Building Component Model Routines

The solution of the model equations is effected by successive calls to WEATHR, the weather simulation routine, AHU, the air handling unit simulation routine, ZONE, the zone simulation routine, COMFRT, the comfort model routine, and CMPILE, the energy use compilation routine. All of the models, with the

exception of ZONE, are steady state models not involving differential equations.

Table 2-10. Sample weather data parameter file

14.0	'Time of maximum temperature, hrs'
0.013	'Humidity ratio
1800.	'Peak solar heat gain on horizontal'
8.0	'Average windspeed, MPH'

WEATHR determines the outside air temperature using a sinusoidal approximation. All other values such as humidity ratio and windspeed are

assumed constant. Solar gain is calculated geometrically. Section 3. describes the equations solved in the weather model.

AHU is used to determine the energy required to heat or cool a mix of return and outdoor air to the supply air setpoint. The model has heating coils, cooling coils, and an outside air damper. These devices are assumed to be under perfect sequenced control. There is no local economizer control of the dampers. Section 4 describes the equations for the air handling unit model.

The ZONE subroutine performs a solution of 5 simultaneous equations of which three are differential equations and two are steady-state. These equations describe the dynamics of heat and moisture transfer between perfectly mixed zone air and a two-node wall and the outside environment. A model of local zone heating or cooling equipment under PI control is included in subroutine ZONE. Details of the solution technique and the equations used in subroutine ZONE are discussed in section 5.

The routine COMFRT compares the current zone space conditions to the ASHRAE comfort zone and determines if the zone is comfortable. The comfort model equations are described in section 6.

The subroutine CMPILE, using values from the state vector, accumulates the energy used by the building in various categories. The equations used to calculate energy are described in section 7.

3. WEATHER MODEL

3.1 Assumptions and Purpose of Weather Model

The purpose of the weather model is to provide values for the dry bulb temperature, humidity ratio, windspeed, and solar radiation on a vertical surface for each timestep in the simulation. It is assumed that tests of an EMCS system will require the generation of one to five days of continuous weather data. For such a time period, all of the days in the period will be assumed to have identical weather. The humidity ratio and windspeed will be assumed to remain constant throughout the test period. The dry bulb temperature is assumed to vary smoothly in a sinusoidal manner with a period of one day. Solar radiation is calculated from geometric relationships and statistical values for direct solar radiation.

Model parameters for the weather model were listed in table 2-10. These parameters allow the weather model to be modified to represent different climates and seasons within climates to which a building might be exposed within the constraints listed above. The parameters for humidity ratio and windspeed specify the constant value that these variables will have throughout the day. Other specific parameters will be discussed in the appropriate sections below.

3.2 Outside Air Temperature

The model parameters which determine the variation of outside dry bulb temperature with time for the weather model are the maximum daily temperature, the minimum daily temperature, and the time of occurrence of the maximum temperature. For the generation of a sinusoidal temperature profile the amplitude, period, offset, and phase of the sinusoid must be specified. For temperature variation the period is assumed to be 24 hours. The amplitude is assumed to be half of the difference between the maximum and minimum daily temperatures and the offset is assumed to be the average of maximum and minimum temperatures. The phase can be determined from the time of occurrence of the maximum temperature.

Rather than a mathematical sine function, the emulator model uses a table of 24 discrete points on a curve. The values in the table are normalized to lie between -1 and +1 with a zero offset. Values between the specified points are obtained by interpolation. The interpolated value is then scaled with the amplitude and offset to obtain the temperature.

3.3 Solar Energy

The effects of solar energy on the building are not included in the abridged model that was produced at NBS. The prediction of solar irradiation on the

building could be added to the model using the equations in the following sections.

3.3.1 Solar Radiation Intensity on the Building Wall

The total solar irradiation on the outer surface of the building wall (including windows) is given by:

$$I = I_b \cos\theta + I_s + I_g \quad (3-1)$$

where I : total solar radiation

I_b : direct radiation

I_s : diffusive radiation

I_g : ground reflective radiation (assume $I_g = 0$)

θ : angle of incidence of the sun's rays

Direct and diffusive radiation are evaluated from the equations given by ASHRAE (1981), p. 27.2, and Walton (1983):

$$I_b = C_L A \exp[-B/\sin(\beta)] \quad (3-2)$$

$$I_s = C I_b \quad (3-3)$$

where C_L is a clearness number between 0.75 and 1.0, β is the solar altitude angle, and A , B , and C are constants. Monthly values are shown in Table 1 of ASHRAE (1981), p. 27.2. Walton (1983) provides a detailed procedure for obtaining A , B , and C for a given Julian date if desired.

3.3.2 Sine of Solar Altitude

$$\sin \beta = \sin(d) \sin(L) + \cos(d) \cos(L) \cos(h) \quad (3-4)$$

where d : declination angle (degrees) [ASHRAE (1981), p. 27.2]

L : latitude (degrees)

h : hour angle (degrees)

β : solar altitude angle (degrees)

The hour angle is given by:

$$h = 15 (t_g - 12 + E/60 + TZN) - \lambda \quad (3-5)$$

where t_g : standard time of day (h)

E : equation of time (min) [ASHRAE (1981), p. 27.2]

λ : longitude (degree)

TZN : time zone number [Kusuda (1976), p. 9a]

= 4 for Atlantic

7 for Mountain

5 for Eastern

8 for Pacific

6 for Central

3.3.3 Cosine of Incident Angle

[ASHRAE (1981), p. 27.3]

$$\cos \theta = \cos(\beta) \cos(\emptyset + Y) \sin(v) + \sin(\beta) \cos(v) \quad (3-6)$$

where θ : angle of incidence of the sun's rays

\emptyset : solar azimuth angle from south

Y : angle between the normal to the vertical surface and the south
(facing angle)

v : tilt angle (the angle between the normal to the surface and the
normal to the ground surface)

$\cos(\beta)$: cosine of solar altitude angle
 $= 1 - \sin^2 \beta$

(3-7)

3.3.4 Sol-air Temperature

The abridged version of the emulator model program uses dry bulb outside air temperature for heat transfer between the wall and the outdoors. A more complete version would use sol-air temperature as given by the following equation for an opaque wall [Threlkeld (1970), p.342]:

$$T_{sol} = T_o + \frac{a I}{U_{ow}} \quad (3-8)$$

where a : solar absorptance of the exposed wall

I : solar radiation intensity (direct + diffuse)

T_o : outside air dry-bulb temperature

U_{ow} : thermal conductance of the wall outside of the mass center

4. AIR HANDLING UNIT MODEL

4.1 Assumptions

The air handling unit model uses steady state air enthalpy calculations to determine the amount of energy required for cooling and heating by the unit. Steady state equations are used since the time step used for the air handling unit model is similar in size to the time constants of HVAC systems. Possible EMCS control actions that provide input to the air handling unit model are starting and stopping the air handling unit, closing or allowing modulation of the outside air dampers, opening or closing minimum outside air dampers, and supply air temperature setpoint. The general model is designed to be configurable to represent either a constant or variable air volume (VAV) unit with either single or dual decks and heat exchangers for heating or cooling. The abridged model (section 2.0) that was implemented in the building emulator model computer program does not allow simulation of dual deck systems or systems with humidity control. See subroutine AHU in APPENDIX.

4.2 Equations

A sample of the model parameters for the air handling unit simulation subroutine was listed in table 2-9. The parameters in the table fall into two categories, which are configuration parameters and analog parameters. The configuration parameters are logical constants which are used to select a particular configuration for the air handling unit. There are four of these parameters, which are DUal-DECK (DUDECK), HUMidity-CONtrol (HUMCON), Return-Air-FAN (RAFAN), and Variable-Air-Volume (VAV), and which may be either true or false.

Figure 2-1 is a diagram of a generalized air handling unit showing the major components of the model. The two basic configurations for the air handling unit are dual-deck or single deck. To select dual deck, the logical parameter DUDECK is set true. If dual deck, there will be a set of heat exchangers for two paths and the supply fan will be located before the split. (Dual deck is not implemented in the abridged model) If the system is single deck, DUDECK will be false, the second set of heat exchangers will not be used, and the supply fan will be located after the last exchanger.

The decks in the model may contain a humidifier, a cooling coil, a heating coil or any combination of the three. The return air fan is optional and the logical parameter RAFAN determines whether it will be included in the model. If the parameter VAV is true, the air handling unit will be modeled as being Variable Air Volume (VAV), and the mass flow rate of air through the unit will be allowed to change to match the zone loading. If humidity control is to be used, parameter HUMCON must be set to true, and the supply air will be maintained at a setpoint for humidity as well as a dry bulb temperature setpoint (humidity control is not implemented in the abridged model).

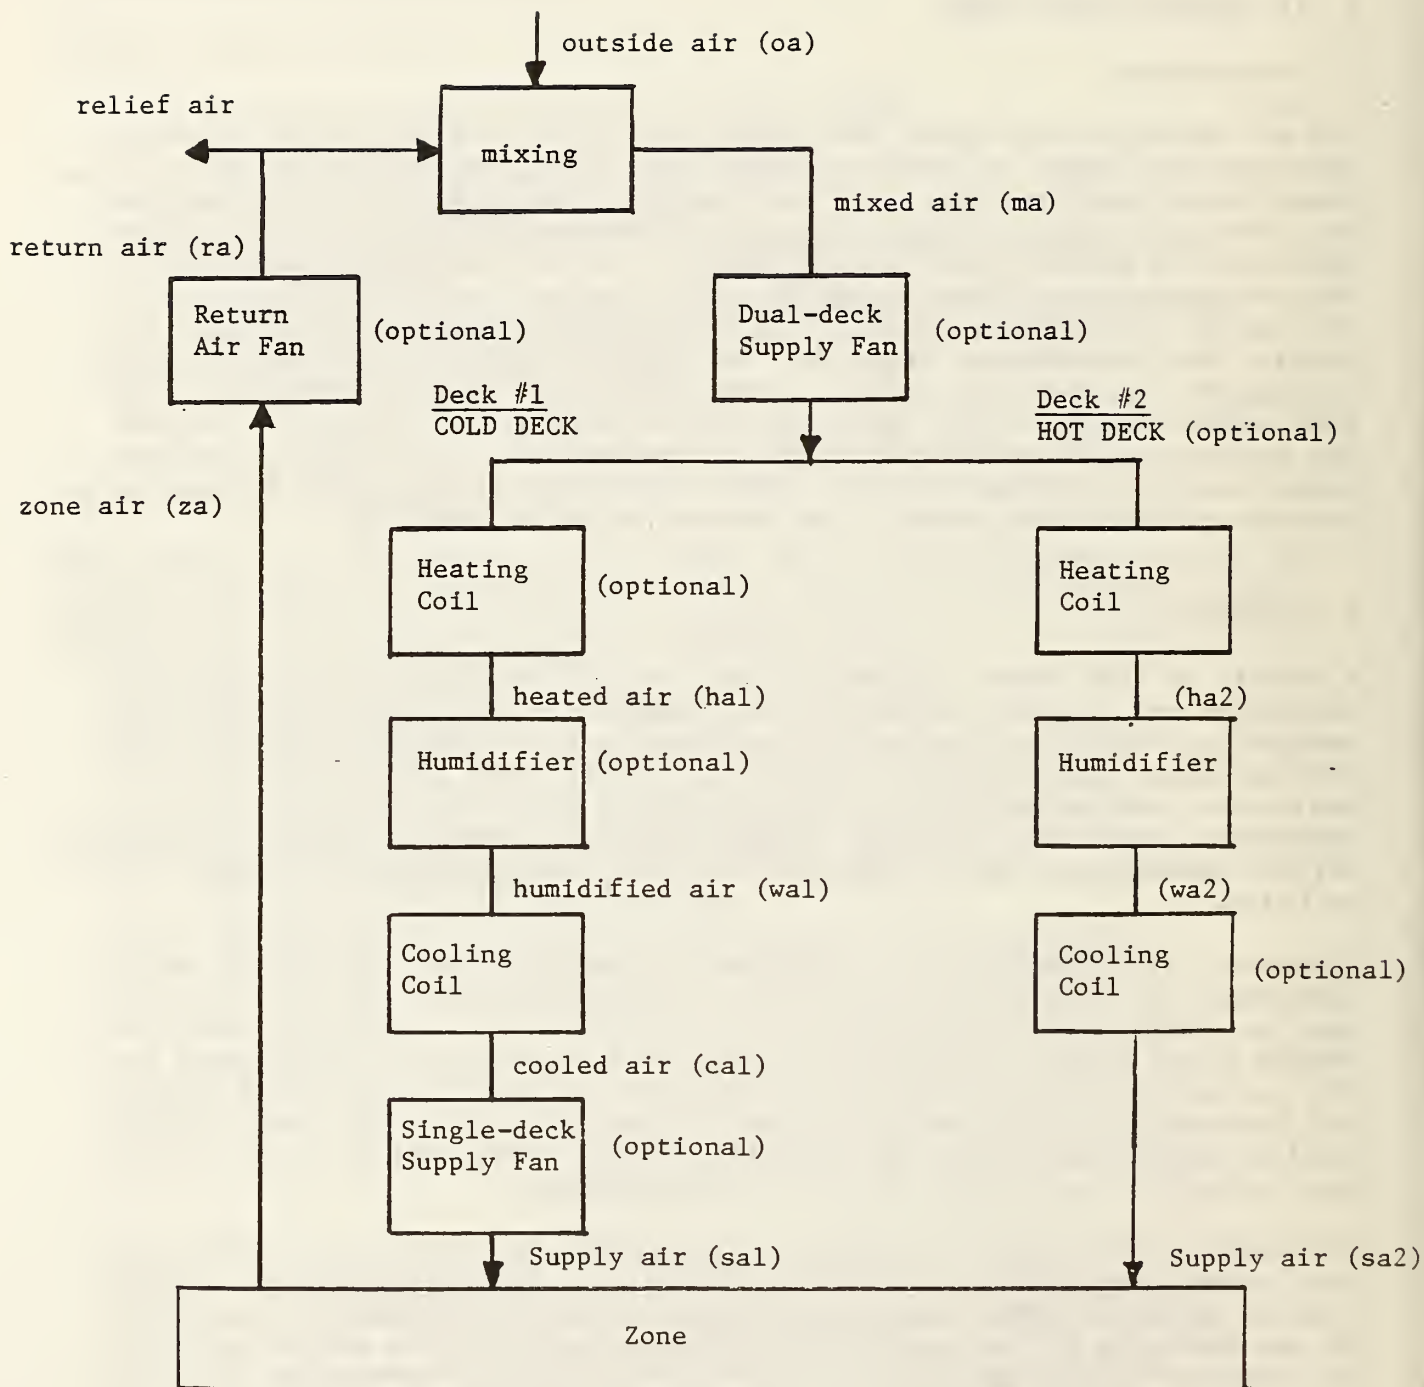

Figure 4-1. Block diagram of components of generalized HVAC system model

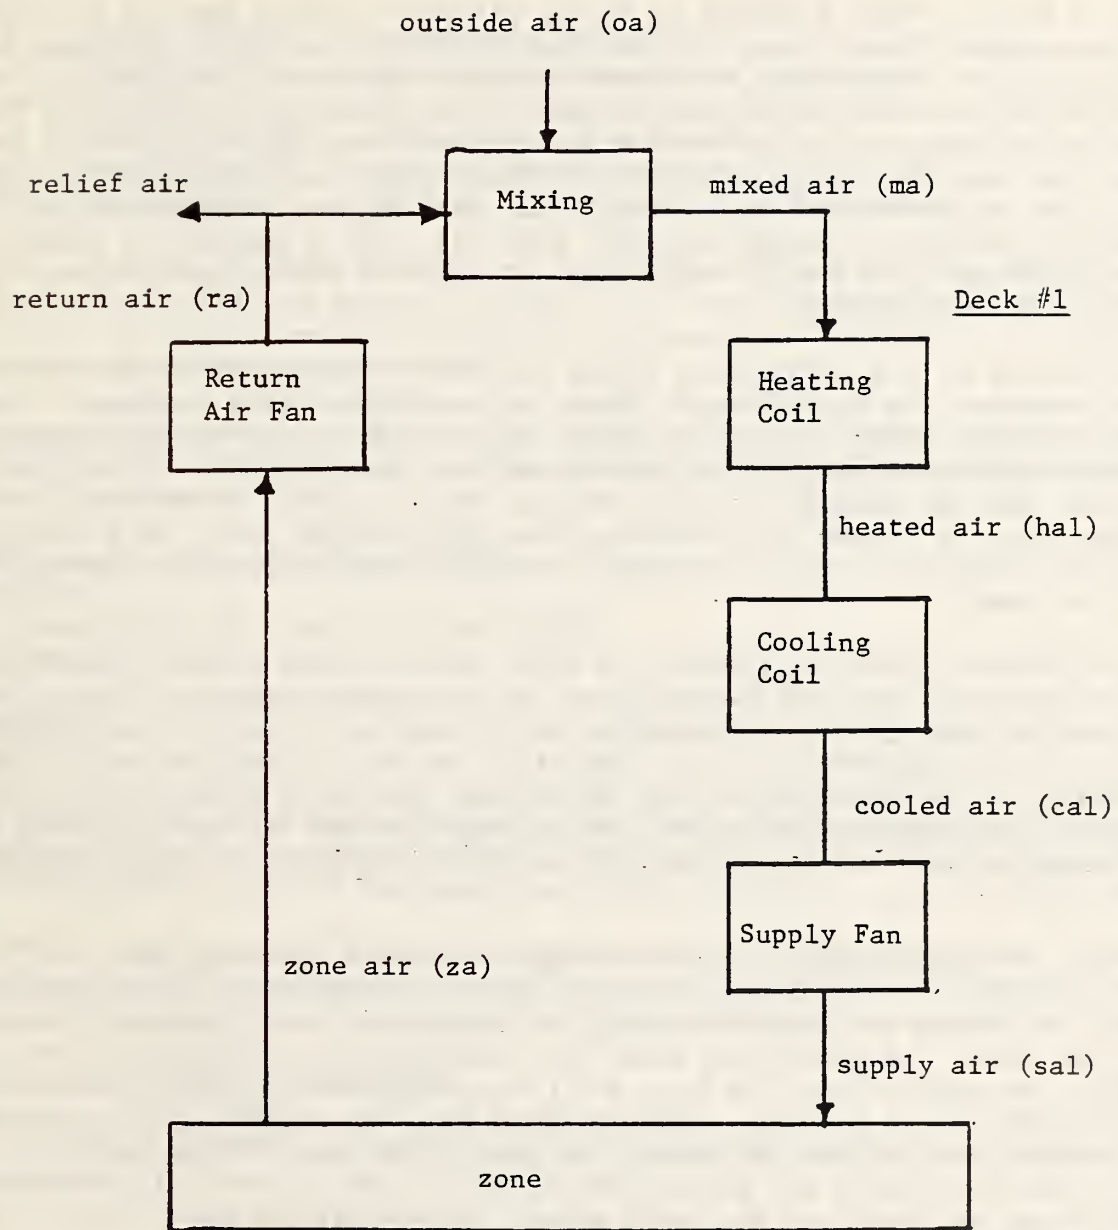

Figure 4-2. Block diagram of components of the abridged, single deck air handling unit model

Table 2-9 also shows a number of analog parameters which have to be specified for the model. These describe the capacities of the coils and fans in the unit. The fans in the unit will have a power requirement, a rated air volume flow rate, and a parameter to specify how much energy was added to the air passing through the fan by the fan waste heat. The fans for VAV will use the rated flow rate as the maximum but will have a flow rate and power consumption which can be lowered to match zone loads. Cooling and heating coils will have a certain capacity in energy per unit time that can be removed or added to the air in the unit. If a coil is given a capacity of zero, this indicates that the coil is not present.

In addition to the parameters there are inputs in the FORTRAN common area which contains the state vector. These are variables which represent commands from the EMCS which is being tested by the emulator. The variable ECONOmizer (ECONO) will be a signal to use or not use the outside air dampers for cooling. UNIT-ON (UNITON) will be true if the unit is to be running and false if the unit is turned off. VENTilation-OFF (VENOFF) will be false during occupied operation, but if the EMCS closes minimum outside air dampers VENOFF will be true.

The locations shown in figure 4-1 with two or three letter abbreviations beside them and location descriptions in parenthesis represent states of the air passing through the air handling unit. Each state can be characterized by the dry bulb temperature, T , the humidity ratio, W , the flow rate m and the enthalpy, h . The abbreviations on the diagram represent subscripts to variable names in the equations which are used to describe the air handling unit model. For example, the temperature of the air returning from the building zones is symbolized by T_{za} .

It will be assumed that if the capacity of the air handling unit will allow, the condition of supply air from the the air handler will be the same as specified by the air handler supply air setpoints. For a constant volume air handling unit, the supply air mass flow rate will be constant. If the system is VAV, the supply air flow rate will be determined by the local equipment model contained in the zone model (section 5.6). The return air flow rate will be assumed to equal the VAV supply air mass flow rate. If the system is dual-deck, the individual air mass flow rates for the hot and cold deck will be determined by the local equipment model. The return air mass flow rate will then equal the sum of the two deck mass flow rates.

The following FORTRAN functions are assumed for psychrometric calculations (the implementations of these functions are described in section 5.5). For the arguments listed, T is dry bulb temperature, W is humidity ratio, P is atmospheric pressure, RH is relative humidity, h is enthalpy, and DP is dewpoint temperature (also see Table 5-3).

1. h = ENTHAL(T, W, P) - enthalpy of moist air
2. T = TEMP(h, W, P) - dry bulb temperature of moist air
3. DP = DEWPT(W, P) - dew point temperature of moist air
4. W = HUMRAT(T, RH, P) - humidity ratio of moist air
5. RH = RELHUM(T, W, P) - relative humidity of moist air
6. T = TDBSAT(h, P) - dry bulb temperature of saturated air

Figure 4-2 is a flow diagram showing the logic which determines the equations to use for calculating the states of the air in the air handling unit. The calculations for each time step are performed based on the return air state which is known from the zone air model.

Since the equations used for the air handling unit model depend on the state of several logical variables, a special format will be used to present the equations. The construction:

```

IF (condition1) is true (or false) THEN
    equation 1
ELSE IF (condition2) is true (or false) THEN
    equation 2
ELSE
    equation 3
ENDIF

```

will be used to denote logical decisions about which equation to use. Indentations will be used for clarity. See Figure 4-2 for logic flow and Table 4-1 for nomenclature of the equations which follow.

The following equations will apply if logical variable UNIT-ON is true. If it is not, then the air handling unit is off, no air is flowing, all mass flow rates will be zero, and all energy use by the air handler will be zero.

```

IF Variable-Air-Volume is true THEN

```

The supply air volume is assumed to be determined by the local zone VAV equipment.

```

ELSE

```

Constant volume is assumed. The mass flow rate m_{sa} equals the rated air flow rate.

```

ENDIF (if Variable-Air-Volume is true).

```

```

IF Return-Air-FAN is true THEN

```

Assume that the return air fan causes a constant amount of thermal energy to be added to the return air per second. The return air fan heating rate must be provided as a parameter, q_{rf} . Then the temperature rise due to the return air fan is:

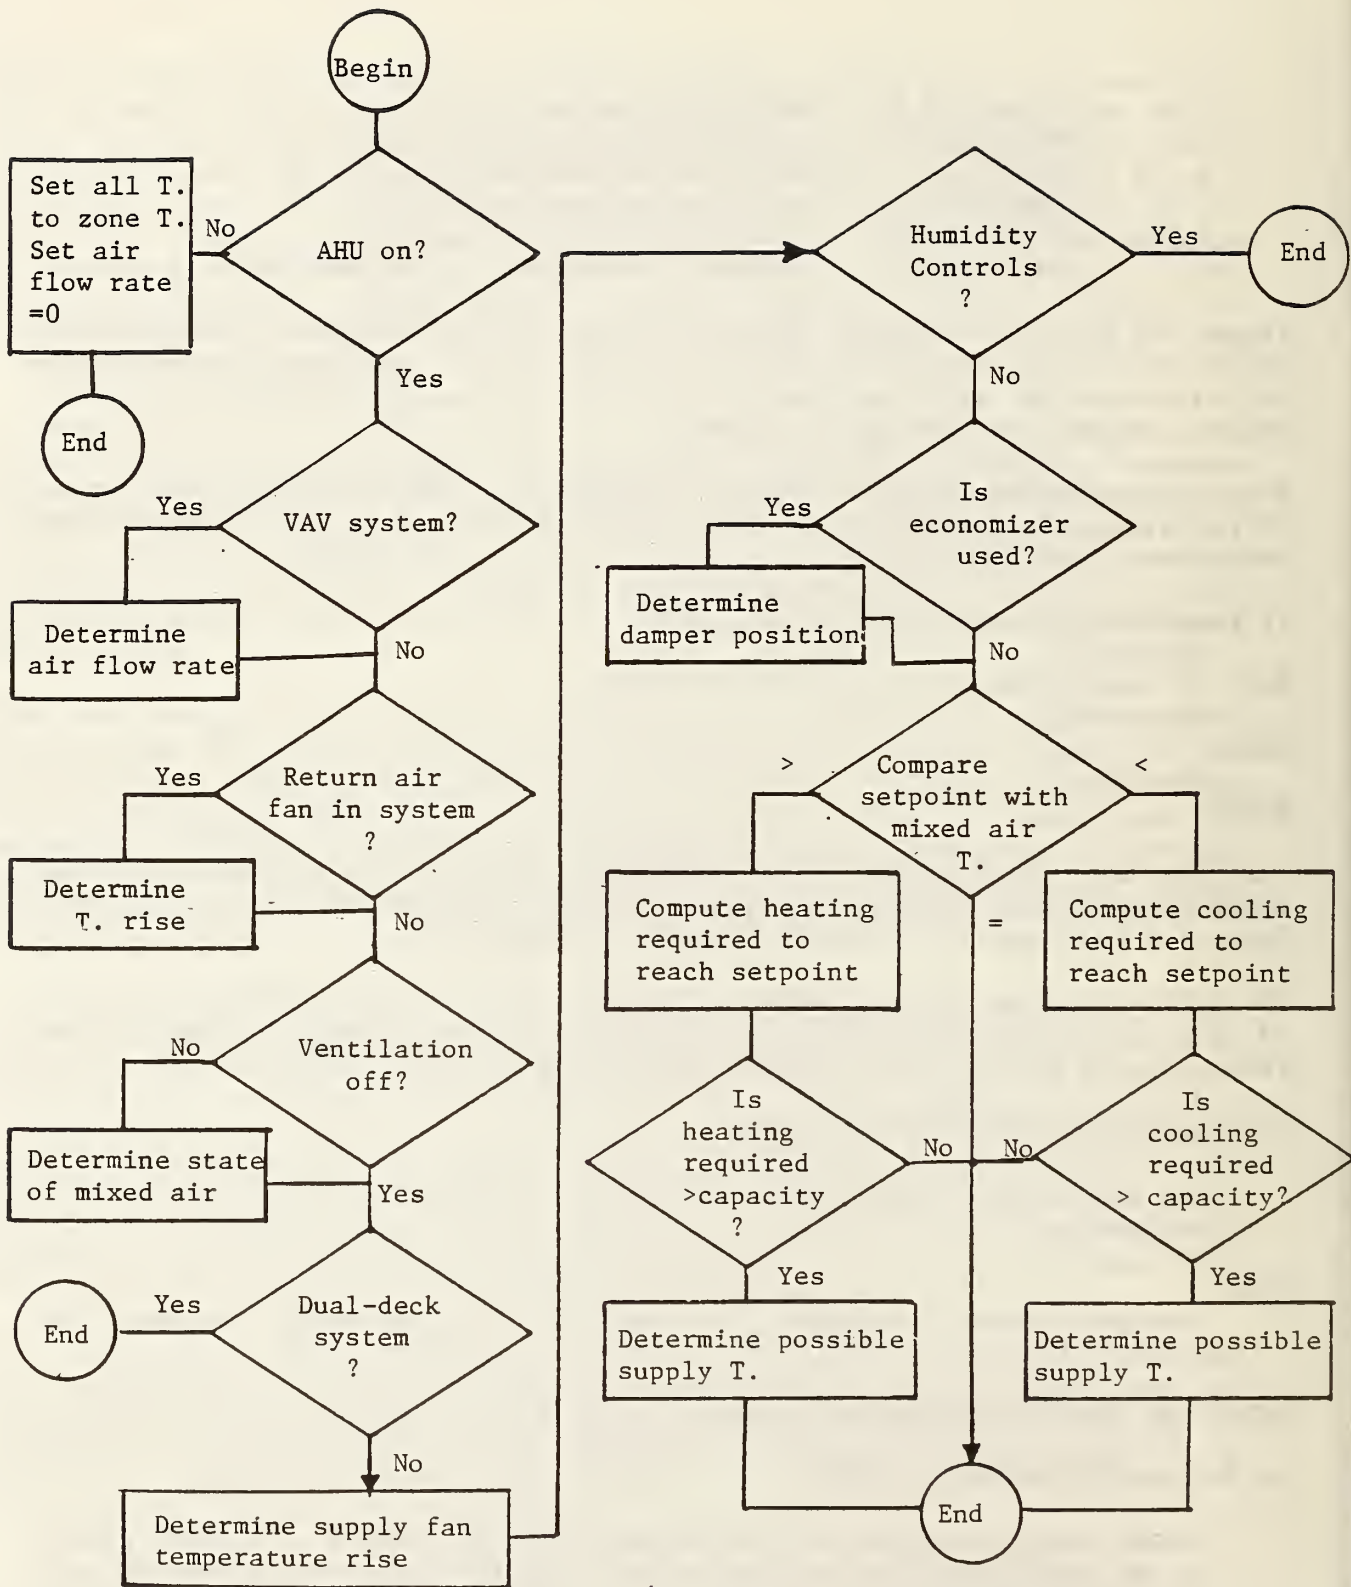

Figure 4-3. Air handling unit model calculation sequence

$$dT_{rf} = \frac{q_{rf}}{m_{ra} c_{pa}} \quad (4-1)$$

$$\text{and } T_{ra} = T_{za} + dT_{rf} \quad (4-2)$$

ELSE

$$T_{ra} = T_{za} \quad (4-3)$$

ENDIF (if Return-Air-FAN is true)

$$W_{ra} = W_{za} \quad (4-4)$$

$$h_{ra} = \text{ENTHAL}(T_{ra}, W_{ra}, P) \quad (4-5)$$

The next calculations determine the state of the mixed air (subscript mc) if the outside air dampers are closed. It will be assumed that f_{va} is a model parameter which the fraction of air mass flow through the air handling unit which is the minimum outside air flow rate for ventilation purposes. If the EMCS cuts off ventilation air as an algorithm action, then this value will be zero:

IF VENTilation-OFF is true THEN

$$h_{mc} = h_{ra} \quad (4-6)$$

$$W_{mc} = W_{ra} \quad (4-7)$$

$$T_{mc} = T_{ra} \quad (4-8)$$

ELSE

$$h_{mc} = f_{va} h_{oa} + (1 - f_{va}) h_{ra} \quad (4-9)$$

$$W_{mc} = f_{va} W_{oa} + (1 - f_{va}) W_{ra} \quad (4-10)$$

$$T_{mc} = \text{TEMP}(h_{mc}, W_{mc}, P) \quad (4-11)$$

ENDIF (if VENTilation-OFF is true)

IF DUAL-DECK is false THEN

For a single deck air handling unit, the supply fan temperature rise is calculated as the return fan rise was calculated:

Table 4-1. Nomenclature for the air handling unit model

c_{pa}	specific heat of air
DP	dew point
dT	temperature rise
f_{va}	fraction of air mass flow for the minimum outside air for ventilation
h	enthalpy
m	air mass flow rate
P	barometric pressure
q	heating/cooling rate
$q_{c,max}$	cooling capacity
$q_{h,max}$	heating capacity
RH	relative humidity
T	air temperature
T_{set}	setpoint temperature
W	humidity ratio

Subscripts:

c	cooling
ca	cooled air
h	heating
ha	heated air
ma	mixed air
mc	state of mixed air if the outside air dampers are closed
mo	state of mixed air if the outside air dampers are completely open
oa	outside air
ra	return air
rf	return air fan
sa	supply air
sf	supply air fan
wa	humidified air
za	zone air

$$dT_{sf} = \frac{q_{sf}}{m_{sal} c_{pa}} \quad (4-12)$$

IF HUMidity-CONTROL is false THEN

If there is no humidity control, there will only be a dry bulb temperature setpoint. The humidity will be allowed to float to any level.

IF ECONOmizer is true THEN

The EMCS allows the air handling unit to use the outside air for conditioning supply air. No provision is made in this version of the model for direct EMCS control of damper position. It is assumed that local controls determine proper outside air damper position. However, once the outside air damper is fully open when cooling is required, it remains open even if outside air enthalpy is high. The EMCS must take responsibility for closing the damper in this case. To determine the outside air damper position:

$$h_{mo} = h_{oa} \quad , \quad (4-13)$$

$$T_{mo} = T_{oa} \quad , \quad \text{and} \quad (4-14)$$

$$W_{mo} = W_{oa} \quad . \quad (4-15)$$

where the mo subscript indicates the state of the mixed air if the outside air dampers are completely open.

If $T_{mc} \leq T_{set} - dT_{sf}$, this indicates that the outside air damper should be closed and that heating of the supply air will be required. In this case:

$$T_{ma} = T_{mc} \quad , \quad (4-16)$$

$$W_{ma} = W_{mc} \quad \text{and} \quad (4-17)$$

$$h_{ma} = h_{mc} \quad . \quad (4-18)$$

However, if $T_{mc} > T_{set} - dT_{sf}$ and $T_{mo} > T_{set} - dT_{sf}$, this indicates that the outside air damper should be wide open, but additional cooling of supply air will be needed using a cooling coil. In this case:

$$T_{ma} = T_{mo} \quad , \quad (4-19)$$

$$W_{ma} = W_{mo} \quad \text{and} \quad (4-20)$$

$$h_{ma} = h_{mo} \quad . \quad (4-21)$$

But, if $T_{mc} > T_{set} - dT_{sf}$ and $T_{mo} \leq T_{set} - dT_{sf}$, then the outside air dampers will be able to provide all conditioning of the air passing through the air handler. In this case, the outside air dampers will be at some intermediate position. The supply air temperature will equal the setpoint but since the fraction of outside air is not known in this case, the exact psychrometric state of the supply air (and thus the enthalpy) is not known. Theoretically, since the dry-bulb temperature lines on the psychrometric chart are not parallel, an iterative

technique would be required to determine W_{ma} and h_{ma} . However, the lines are approximately parallel and an approximate relationship can be used since the state of the mixed air lies on a straight line between the state of the air with the dampers fully open and the state with the dampers closed. This is described by

$$\frac{T_{ma} - T_{mo}}{T_{mc} - T_{mo}} = \frac{W_{ma} - W_{mo}}{W_{mc} - W_{mo}} \quad \text{or} \quad (4-22)$$

$$\text{Then, since: } T_{ma} = T_{set} - dT_{sf} \quad , \quad (4-23)$$

$$W_{ma} = \frac{W_{mc} - W_{mo}}{T_{mc} - T_{mo}} (T_{set} - dT_{sf} - T_{mo}) + W_{mo} \quad (4-24)$$

$$h_{ma} = \text{ENTHAL}(T_{ma}, W_{ma}, P) \quad (4-25)$$

ELSE

If the EMCS keeps the outside air dampers closed:

$$T_{ma} = T_{mc} \quad , \quad (4-26)$$

$$W_{ma} = W_{mc} \quad \text{and} \quad (4-27)$$

$$h_{ma} = h_{mc} \quad . \quad (4-28)$$

ENDIF (ECONOmizer is true)

If outside air is providing all of the conditioning, as determined above ($T_{ma} = T_{set} - dT_{sf}$), then no heating or cooling of the mixed air is required, and:

$$T_{cal} = T_{ma} \quad , \quad (4-29)$$

$$W_{cal} = W_{ma} \quad , \quad (4-30)$$

$$h_{cal} = h_{ma} \quad , \quad (4-31)$$

$$T_{hal} = T_{ma} \quad , \quad (4-32)$$

$$W_{hal} = W_{ma} \quad , \quad \text{and} \quad (4-33)$$

$$h_{hal} = h_{ma} \quad . \quad (4-34)$$

However, if heating of the mixed air is required ($T_{ma} < T_{set} - dT_{sf}$) then the air must be heated from T_{ma} to T_{hal} , where:

$$T_{hal} = T_{set} - dT_{sf}. \quad (4-35)$$

The simplified psychrometric process for air heating is to increase the temperature of the air at constant humidity ratio (no moisture is added). Therefore:

$$W_{hal} = W_{ma} \quad \text{and} \quad (4-36)$$

$$h_{hal} = ENTHAL(T_{hal}, W_{ma}, P). \quad (4-37)$$

Then the energy added to the air is:

$$q_h = m_{sal} (h_{hal} - h_{ma}). \quad (4-38)$$

If q_h is greater than the heating capacity of the air handling unit, then the supply air temperature will be below the supply air setpoint. The supply air temperature is calculated as follows:

$$h_{hal} = \frac{q_{h,max}}{m_{sal}} + h_{ma}, \quad \text{and} \quad (4-39)$$

$$T_{hal} = T(h_{hal}, W_{ma}, P). \quad (4-40)$$

Then the energy added to the air is:

$$q_h = q_{h,max} \quad (4-41)$$

Alternatively, cooling of the air may be required ($T_{ma} > T_{set} - dT_{sf}$). Then the air must be cooled from T_{ma} to T_{cal} , where:

$$T_{cal} = T_{set} - dT_{sf}. \quad (4-42)$$

The assumed psychrometric process for air cooling is to remove energy from the air at constant humidity ratio until the dew point temperature of the mixed air is reached, at which point energy and water are removed from the air, which remains saturated, until T_{cal} is reached.

The dewpoint temperature must be known for the calculations:

$$DP_{ma} = DEWPT(W_{ma}, P) \quad (4-43)$$

If $T_{cal} > DP_{ma}$, then the supply air will not be at a saturated condition after it is cooled and:

$$h_{cal} = h(T_{cal}, W_{ma}, P) , \text{ and} \quad (4-44)$$

$$W_{cal} = W_{ma} . \quad (4-45)$$

However, if $T_{cal} \leq DP_{ma}$ then condensation of moisture from the air will occur and the supply air will be assumed to be saturated:

$$RH_{cal} = 100 \% , \quad (4-46)$$

$$W_{cal} = HUMRAT(T_{cal}, RH_{cal}, P) , \quad \text{and} \quad (4-47)$$

$$h_{cal} = ENTHAL(T_{cal}, W_{cal}, P) . \quad (4-48)$$

Then the cooling energy required to maintain the setpoint is:

$$q_c = m_{sal} (h_{ma} - h_{cal}) \quad (4-49)$$

If q_c is larger than the rated capacity of the cooling coil, then the supply air state will be above the setpoint of the air handling unit. The supply air state and cooling energy will then have to be calculated as follows:

$$h_{cal} = h_{ma} - \frac{q_{c,max}}{m_{sal}} , \text{ and} \quad (4-50)$$

$$q_c = q_{c,max} \quad (4-51)$$

If $h_{cal} > ENTHAL(DP_{ma}, W_{ma}, P)$, then the supply air at maximum cooling capacity is not saturated:

$$T_{cal} = TEMP(h_{cal}, W_{ma}, P), \text{ and} \quad (4-52)$$

$$W_{cal} = W_{ma} . \quad (4-53)$$

However, if $h_{cal} \leq h(DP_{ma}, W_{ma}, P)$, then the supply air at maximum cooling capacity is saturated:

$$T_{cal} = TDBSAT(h_{cal}, P), \text{ and} \quad (4-54)$$

$$W_{cal} = HUMRAT(T_{cal}, RH=100\%, P) \quad (4-55)$$

The final supply air state is then:

$$W_{sal} = W_{cal} \quad (4-56)$$

$$T_{sal} = T_{cal} + dT_{sf} \quad (4-57)$$

$$h_{sal} = \text{ENTHAL}(T_{sal}, W_{sal}, P) \quad (4-58)$$

ELSE

If it is in the heating season and the humidity is too low, a humidifier can be used to increase the humidity ratio of the supply air. If it is in the cooling season and humidity is excessive, the air can be dehumidified by overcooling and reheating of air. Humidity control was not implemented in the abridged version of the emulator model and equations will not be presented.

ENDIF (if HUMidity-CONTROL is false)

ELSE

Equations for dual deck were not implemented in the abridged version of the emulator model and will not be presented.

ENDIF (if DUAL-DECK is false)

The states of the air passing through the air handling unit are stored in the state vector and are made available to other model subroutines in the building emulator model program.

5. BUILDING SPACE ZONE MODEL

The building zone model subroutine, unlike the other model equation subroutines, implements a model formulated in terms of differential equations. A dynamic rather than a steady-state model is necessary since the time step magnitude used in the model (smaller than one minute) is much smaller than the characteristic time constants of the zone.

5.1 Assumptions

A number of simplifying assumptions are made in order to allow a relatively simple set of model equations. The building zone to be modeled is assumed to be a typical perimeter zone of a large multi-story building as Kao (1983) used in his energy conservation study for a large office building. The zone is enclosed by an exposed wall with a glass window, three interior walls, ceiling, and floor. Since there is one exposed wall and one glass window the governing equations are simplified. The following assumptions are made for the building zone model:

- (1) Uniform temperature distributions on surfaces.
- (2) No stratification of zone air (fully mixed air).
- (3) No heat or mass flow between zones.
- (4) Simple, uniform optical and thermal properties for any glass windows.
- (5) The term 'wall' includes walls, ceiling, and floor.
- (6) All wall structures (including ceiling and floor) which are not exposed directly to the outside are treated as thermally adiabatic. (No conductive heat flow across the wall structure is assumed).
- (7) Simple two-node representation of the exterior wall with one node at the interior wall surface and one node at the mass center point of the wall.
- (8) Convective and radiative heat transfer coefficients for the inner surfaces of walls are considered constant.
- (9) The surface heat transfer coefficient of outside wall surfaces is considered constant and is not a function of outdoor conditions (including wind).
- (10) The wind speed is considered constant and has an influence only on infiltration.

- (11) All static pressures in the HVAC system, zone and outdoor air are assumed to be constant with a value of 29.92 inches of mercury.
- (12) The latent heat gain from furnishings in the zone is neglected.
- (13) The heat capacity of zone furnishings is assumed to remain the same at all times.
- (14) Radiant heat from lights (short wave radiation) is assumed to be uniformly distributed on all inner surfaces of the zone.
- (15) For all glass windows, the same constant values of transmittance and shading coefficient are used.
- (16) For all exposed opaque walls, solar absorptance is a constant.
- (17) Solar radiation intensity consists of direct and diffuse radiation. Ground reflective radiation is ignored. The solar constants A, B, and C appearing in equations (3-2) and (3-3) are assumed constant for a given specific month.
- (18) It is assumed that solar radiation entering the zone through windows is not absorbed by glass but is distributed uniformly on the inner surfaces of the zone.

Based on these assumptions, it is assumed that five state variables are sufficient to model the zone. The state variables are room air dry bulb temperature, room humidity ratio, exterior wall interior surface temperature, glass interior surface temperature, and exterior wall internal temperature.

The abridged model (see section 2) implemented in the building emulation simulation program included some additional assumptions. The equations presented in the following sections will usually be for a complete model. The changes to equations for the abridged model will be described whenever necessary in the following sections. The assumptions for the abridged model are:

- 1) No effects of solar energy.
- 2) No radiative heat transfer between zone surfaces.

5.2 Fundamental Equations

Since there are five state variables in the building emulator, five equations relating to these variables are required to solve for the values of the variables. Table 5-1 contains nomenclature for the fundamental equations of the zone model.

5.2.1 Zone Air Heat Balance

The first fundamental equation for the emulator zone model expresses the balance in heat transfer between the air and furnishings in the zone and the wall and window surfaces, entering supply air from the air handling unit, infiltration heat transfer, and internal sources of heat [Borresen (1981), Modest and Macken (1977), Bullock (1984), Park (1981)]. The equation is:

$$C_{\text{zone}} \frac{dT_i}{dt} = Q_{\text{supply}} + Q_{\text{infiltration}} + Q_{\text{convection}} + Q_{\text{internal}} \quad (5-1)$$

The left hand side of the equation represents the storage of energy in the zone air and furnishings. The state variable is the interior air temperature. Of the four terms on the right side of the equation, the energy from the supply air and the internal gains may be considered boundary conditions. The supply air condition is determined by the air handling unit model and the internal gain, consisting of heat gains from occupants, lights, and equipment, is determined by the building schedule. The other two terms for convection and infiltration heat transfer are functions of the other state variables.

Table 5-1. Nomenclature for equations in the building space zone model

State Variables:

T_i	- space dry bulb temperature	W_i	- space humidity ratio
T_w	- wall mass center temperature	T_{ig}	- window glass temperature
T_{iw}	- wall interior surface temperature		

Other Parameters:

A	- conduction coefficient	B	- convection coefficient
C	- thermal mass	T	- temperature
M_{air}	- air mass for water absorption	Q	- heat transfer rate
T_{mr}	- space mean radiant temperature	R	- radiative coefficient
G	- zone moisture increase rate		
S_{gw}	- wall heat gain by solar radiation through windows		

Subscripts:

convec	- convection	o	- outside air	g	- glass
infiltration	- infiltration	w	- at the wall mass center		

5.2.2 Exterior Wall Mass Heat Balance

The exterior wall is assumed to be the only surface enclosing the zone which exchanges energy with the outdoor environment and the indoor environment. The state variable for wall temperature is assumed to be the temperature at the

mass center of the wall. The mass center is defined as that point in the wall where for a unit area of wall the total mass of the wall outside of the mass center is equal to the total mass of the wall inside the mass center. For a masonry construction, this may result in the mass center being different from the geometric center of the wall. The equation for the exterior wall is:

$$C_{\text{wall}} \frac{dT_w}{dt} = Q_{\text{inside}} + Q_{\text{outside}} + Q_{\text{solar}} \quad (5-2)$$

The left hand side of the equation represents the storage of energy in the building wall. The first term on the right is the heat transfer between the wall interior and the inner wall surface. This term is dependent on state variables. The second two terms on the right represent the heat transfer between the wall interior and the outdoor environment, including the impingement of solar irradiation on the outside of the wall. The right two terms are time-dependent boundary conditions.

5.2.3 Zone Air Moisture Balance

The air in the zone is assumed to contain moisture. The state variable used to describe the water content of the air is the humidity ratio. The equation used to describe the moisture balance is [Chi (1982), Bullock (1984)]:

$$M_{\text{air}} \frac{dW_i}{dt} = G_{\text{infilt}} + G_{\text{supply}} + G_{\text{internal}} \quad (5-3)$$

The left hand side of this equation represents the storage of water vapor in the air and furnishings of the zone. The right hand side of the equation has three terms. The first term is the moisture transfer with the outdoor environment due to infiltration, which contains a state variable. The second term is the net moisture added to or removed from the room by the air handling unit. This is the difference in absolute moisture between the supply and return air from the air handling unit, and is a boundary condition. The third term is the moisture generated internally by occupants and equipment. The deficiency in this equation is that it assumes the air and furnishings can absorb an infinite amount of moisture when in reality, the air can become saturated. The emulator model zone subroutine performs a check of the relative humidity of the air to prevent oversaturation.

5.2.4 Inner Wall Surface Heat Balance

For the inner wall surface of the exterior wall, the heat balance is expressed by an algebraic equation rather than a differential equation since there is no storage of energy at the wall surface. The equation is:

$$A_w(T_w - T_{iw}) + B_w(T_i - T_{iw}) + R_w(T_{mr} - T_{iw}) + S_{gw} = 0 \quad (5-4)$$

This equation is based on the assumption that all heat transfer in and out of the node at the wall surface sums to zero. The first term is the conduction heat transfer between the wall interior and the inner wall surface. A_w is a conduction coefficient. The second term is the convection heat transfer between the wall surface and the zone mean radiant temperature. The final term is due to any solar irradiated energy which passes through the zone window and is absorbed by the zone inside surfaces.

5.2.5 Inner Glass Surface Heat Balance

For the inner glass surface of the zone window, if present, an algebraic equation describes the heat transfer balance since there is no storage of energy:

$$A_g(T_o - T_{ig}) + B_g(T_i - T_{ig}) + R_g(T_{mr} - T_{ig}) = 0 \quad (5-5)$$

This equation expresses that the sum of all heat transfer in and out of the node at the glass surface is zero. The first term is the conduction/convection heat transfer between the inner glass surface and the outdoor air. The coefficient A_g is a combination convection and conduction coefficient. The second term in the equation is the convection heat transfer between the glass surface and the interior air. The coefficient B_g is for convection. Radiant heat transfer between the glass surface and the mean radiant temperature of the room is represented by the third term of the equation.

5.3 Solution of Equations

The equations described in section 5.2 are solved by the zone model subroutine using a simple explicit forward difference numerical technique (Euler method) to predict the values of the state variables one step forward in time. The time step used within the zone model is different from the emulator time step used for the other models in the emulator simulation program. Since simple differential equation solution technique is used within the zone model, the time steps must be small or the solution will not converge. The emulator time step is divided into a number of smaller zone model time steps and the differential equations are solved for each zone model time step until the

emulator time step has passed. However, the zone model is not constrained to execute zone model time steps in real time.

The subroutine ZONE performs the steps required to determine the values of the state variables at the next emulator time step. This routine first determines the best value for the zone model time step. This process is described in section 5.3.2. Then ZONE calls the two subroutines EULER and SURFAC in sequence, and advances the time by one zone model time step until the emulator time step has passed. The subroutine EULER is used to solve the three differential equations listed above (5-1 through 5-3) for one zone model time step. SURFAC determines the wall and glass surface temperatures for the current time step using the algebraic equations described above (5-4 through 5-5).

5.3.1 Euler Forward Difference Technique

The subroutine EULER is a generalized routine to advance a system of ordinary first order differential equations by one time step using the explicit difference method. The arguments to the routine include the number of differential equations, an array containing the dependent (state) variables, the time step, and the name of a FORTRAN function which will evaluate the right hand sides of the differential equations when they are expressed in the form:

$$\frac{dY_i}{dt} = f(t, Y_1, Y_2, \dots, Y_n), i=1,2,\dots,n \quad (5-6)$$

where Y_i is the i th dependent variable and n is the number of equations. The value of Y at time $t + \Delta t$ can approximately be predicted by:

$$Y_i(t + \Delta t) = Y_i(t) + \Delta t * \text{FUNCTION}(i, t, n, Y_1, Y_2, \dots, Y_n) \quad (5-7)$$

As long as the product of the time step Δt and the function value is small, a solution to the differential equations can be obtained.

5.3.2 Adaptive Time Step

The time step used by the EULER subroutine is determined adaptively to become smaller when the zone is undergoing rapid changes in the state variables and larger as the zone approaches steady state. Subroutine ZONE estimates a new time step each time it is called. The estimation is based on the requirement that the change in any state variable for one Euler time step must not exceed a selected maximum value. For example, in the building emulator model program, this maximum has been chosen to be 0.1 degrees F for temperature state variables. Since the value of the function which describes the right hand side of the differential equation (described in section 5.3.1) is the rate of

change of the state variable, the smallest desirable zone model time step may be determined by dividing the maximum allowable change in the state variable per time step by the current value of the right hand side function. Of course, calculations must be performed to ensure that the zone model time step is not larger than the emulator time step or smaller than a certain minimum. In the building emulator program zone model subroutine the time step can be no smaller than 0.001 seconds.

After the zone model time step is determined, it is adjusted so that it evenly divides the emulator time step. The quotient of this division is the number of times that the ZONE subroutine must call the EULER and SURFAC subroutines for each emulator model time step.

5.3.3 Differential Equation Function

The FORTRAN function ZONEFN is used by the zone model subroutine to calculate the current value of the right hand sides of the differential equations describing the state variables. Since there are three differential equations for the zone model, there are three possible right hand sides of the differential equations. The right hand side to be calculated is determined by an index which is 1 for the zone air energy balance, 2 for the zone moisture balance, and 3 for the wall energy balance. The expanded right hand sides of the equations corresponding to equations (5-1 through 5-3) are presented below. The variables which are designated by an upper case F with a subscript are implemented in the ZONEFN subroutine in a special way. Rather than being variables or constants, they are FORTRAN functions which return the value of a coefficient or energy term. In the definition of terms following each equation below, the FORTRAN function name used in the emulator model program will be listed. For the zone air energy balance:

$$\text{ZONEFN} = \frac{F_{sa} + F_I(T_o - T_i) + F_{cw}(T_{iw} - T_i) + F_{cg}(T_{ig} - T_i) + F_{ig}}{F_{cz}} \quad (5-8)$$

where: F_{sa} : energy entering or removed from the zone by the air handling unit (function SUPPLY).
 F_I : coefficient for infiltration of outdoor air into zone (function INFILT).
 F_{cw} : coefficient for convection between the exterior wall surface and the zone air (function CONVWA).
 F_{cg} : coefficient for convection between the surface of a window in the exterior wall and the zone air (function CONVGL).
 F_{ig} : energy entering the zone due to internal gains from lights, equipment, and people (function INTERN).
 F_{cz} : thermal mass of the zone air and furnishings (function MASSTH).

For the zone moisture balance:

$$\text{ZONEFN} = \frac{F_{sw} + F_{Im}(W_o - W_i) + F_{mg}}{F_{mz}} \quad (5-9)$$

where: F_{sw} : moisture added to or removed from the zone by the air handling unit (function SUPPLW).
 F_{Im} : coefficient for infiltration of moisture (or exfiltration) from outdoor air into zone (function INFILW).
 F_{mg} : moisture entering the zone due to internal moisture gain from equipment and people (function MOIST).
 F_{mz} : effective mass of zone air and furnishings which can absorb moisture (function MASSA).

for the prediction of the rate of change of moisture in the zone, an additional check is made to insure that the zone air does not become oversaturated. This is accomplished by first using the function HUMRAT to determine the humidity ratio at the zone air temperature, T_i , and 100 percent relative humidity. If the current indoor humidity ratio, W_i , exceeds this value and ZONEFN is a positive value, then ZONEFN is set to zero, indicating that no further increase in zone moisture is possible. If W_i is zero and ZONEFN is negative, ZONEFN is set to zero indicating that zone moisture cannot be decreased since the air in the zone is completely dry.

The right hand side function for the exterior wall mass heat balance is:

$$\text{ZONEFN} = \frac{F_{co}(T_{sol} - T_w) + F_{ci}(T_{iw} - T_w)}{F_{cw}} \quad (5-10)$$

Where: F_{co} : coefficient for conduction and convection heat transfer between the mass center of the wall and the outdoor air (function CNDCTO).
 F_{ci} : coefficient for conduction heat transfer between the mass center of the wall and the inner surface of the wall (function CNDCTI).
 T_{sol} : the sol-air temperature (defined in section 3.3.4)
 F_{cw} : thermal mass of the wall structure (function MASSW).

5.3.4 Surface Heat Balance Subroutine

The subroutine SURFAC is called by ZONE to solve the algebraic equations (5-4) and (5-5) for the inner surface temperatures of the exterior wall and glass window. The two equations after rearrangement to solve for the surface temperatures are shown below. The variables which are designated by an upper case F with a subscript are implemented in the SURFAC subroutine in a special

way. Rather than being variables or constants, they are FORTRAN functions which return the value of a coefficient or energy term. In the definition of terms following each equation below, the FORTRAN function name used in the emulator model program will be listed. For the exterior wall inner surface balance:

$$T_{iw} = \frac{F_{Aw} T_w + F_{Bw} T_i + F_{Rw} F_{Tr} + F_{ts}}{F_{Aw} + F_{Bw} + F_{Rw}} \quad (5-11)$$

Where: F_{Aw} : coefficient for conduction heat transfer between inner surface of wall and mass center of wall (function CNDCTI).
 F_{Bw} : coefficient for convection heat transfer between inner surface of wall and zone air (function CONVWA).
 F_{Rw} : coefficient for radiation heat transfer between inner surface of wall and zone radiant temperature (function WRADIA).
 F_{Tr} : mean radiant temperature of zone (function TRN).
 F_{ts} : energy which passes through windows in the zone and is absorbed at the wall surface (function WSOLAR).

For the window glass inner surface heat balance:

$$T_{ig} = \frac{F_{Ag} T_o + F_{Bg} T_i + F_{Rg} F_{Tr}}{F_{Ag} + F_{Bg} + F_{Rg}} \quad (5-12)$$

Where: F_{Ag} : coefficient for conduction and convection heat transfer between the inner surface of the glass and the outdoor air (function GCNDCT).
 F_{Bg} : coefficient for convection heat transfer between the inner surface of the glass and the zone air (function GCNVCT).
 F_{Rg} : coefficient for radiation heat transfer between the inner surface of the glass and the zone radiant temperature (function GRADIA).
 F_{Tr} : mean radiant temperature of zone (function TRN).

5.3.5 Fortran Coefficient Functions

The names of the special FORTRAN functions used to give coefficients or terms in the equations (5-8) through (5-12) were listed in the definitions following the equations. All of these functions have the same general form. The functions can be designated as either time-dependent or time-independent. Values of coefficients such as conduction coefficients may be considered time-independent and will need to be calculated only once. In this case, the function automatically determines if the function has already been evaluated and if so, returns the previously determined value.

Other coefficients such as a coefficient for infiltration heat transfer must usually be considered time-dependent. In this case the coefficient will be calculated each time the function is called unless the function is called twice for the same time step. In this case the function returns the previously determined value.

The general form of the FORTRAN function for a coefficient function is shown in table 5-1. The parameter TIMEDP is set to true for a time-dependent function and false for a time-independent function. The specific equations to evaluate the functions used in the emulator model program are listed in section 5.4.

5.4 Equations for Heat and Mass Transfer Coefficients and Terms

The following sections contain the equations used to evaluate the terms and coefficients to expand equations (5-8) through (5-12). The name of the FORTRAN coefficient function (see section 5.3.5) will be given in parenthesis following the title of the section. The equations listed would be placed in the area marked 'equations to evaluate function' in the generalized coefficient function listing in table 5-2.

5.4.1 Sensible Heat Gain/Loss from Supply Air (SUPPLY)

The energy added to or removed from the zone by the supply air is determined from the difference in enthalpies of return and supply air. In addition, the energy which is added to or removed from the room by the local zone heating or cooling equipment is included. The equation used is:

$$F_{sa} = h_{sa1} m_{sa1} + h_{sa2} m_{sa2} - h_{za} m_{ra} + Q_{lh} - Q_{lc} \quad (5-13)$$

Where: h_{sa1} : enthalpy of supply air
 m_{sa1} : mass flow rate of supply air
 h_{sa2} : enthalpy of hot deck supply air (optional)
 m_{sa2} : mass flow rate of hot deck supply air (optional)
 h_{za} : enthalpy of zone air
 m_{ra} : mass flow rate of return air
 Q_{lh} : energy added to zone by local zone heating equipment
 Q_{lc} : energy removed from zone by local zone cooling equipment

This function is considered to be time-dependent.

5.4.2 Coefficient for Sensible Heat Gain/Loss due to Infiltration (INFILT)

Sensible gain/loss due to infiltration is assumed to equal a coefficient multiplied by the difference in temperature between zone and outdoor air. The coefficient is determined from:

$$F_I = C_{p,inf1} \rho_{inf1} V_i I_{air} \quad (5-14)$$

where $C_{p,inf1}$: specific heat of infiltrated air
 ρ_{inf1} : density of infiltrated air
 I_{air} : air exchange rate (air changes/second)
 V_i : volume of zone space

The air exchange rate is considered to be a function of windspeed and indoor-outdoor temperature difference [Kusuda and Saitoh (1980), Achenbach and Coblenz (1963)]. The equation for air exchange rate per hour is:

$$I_{air} = \frac{I_{s,air}}{0.695} [0.15 + 0.013 V_w + 0.005 |T_o - T_i|] \quad (5-15)$$

where V_w : wind speed (mph)
 $I_{s,air}$: standard air exchange rate (model parameter, see table 2-8)
 = 1.5 for leaky building
 1.0 for standard building
 0.5 for modern type building

This function is considered to be time dependent.

5.4.3 Coefficient for Convective Heat Flow Rate from Walls (CONVWA)

The convective heat flow rate from the inner surface of the zone walls, including floor and ceiling, is assumed to be equal to a coefficient

multiplied by the difference between the wall surface temperature and the zone air temperature. The coefficient is given by:

$$F_{cw} = h_{iw,c} A_w \quad (5-16)$$

where $h_{iw,c}$: convective heat transfer coefficient at the interior surface
(model parameter, see table 2-8)
 A_w : surface area of the wall (model parameter, see table 2-8).

This coefficient is assumed to be time-independent.

5.4.4 Convective Heat Flow Rate from Glass Windows (CONVGL)

The convective heat flow rate from the inner glass surface of zone windows is assumed to be equal to a coefficient multiplied by the difference between the glass surface temperature and the zone air temperature. The coefficient is given by:

$$F_{cg} = h_{ig,c} A_g \quad (5-17)$$

where $h_{ig,c}$: convective heat transfer coefficient of inner glass
surface to zone air
 A_g : the glass window area

This coefficient is assumed to be time-independent. The abridged zone model effectively assumes that there are no windows in the zone, and therefore this coefficient is not used.

5.4.5 Sensible Internal Gains (INTERN) and Latent Internal Gains (MOIST)

5.4.5.1 Internal Gain Schedule Table

The FORTRAN functions used to determine internal gains, INTERN and MOIST, determine their values from a table which was created during the emulator model initialization. The table contains internal gain as a function of time-of-day. Interpolation is not used with the table and therefore the internal gain is not a continuous function of time. Internal gains remain at a constant level until changed by the next entry in the table at a particular time. The internal gain schedule table is stored in five FORTRAN arrays. The arrays contain time-of-day, sensible heat gain from equipment at the corresponding time-of-day, sensible heat gain from people, moisture gain from equipment and moisture gain from people. A function SCHED is used to determine a sensible or moisture gain from the internal gain tables. If moisture gain is requested (by MOIST), SCHED returns the sum of the moisture gain from people and equipment.

If a sensible gain is requested (by INTERN), SCHED returns the sum of the sensible gains from people and equipment.

5.4.5.2 Determining Values for the Internal Gain Schedule Table

The values in the internal gain schedule table are created during the initialization process of the emulator model. An example input parameter file was given in table 2-7. The following equations show how a row in the schedule table is created from the information in a line of table 2-7.

5.4.5.2.1 Convective Heat Gain from People

The internal gain from a person is assumed to depend only on the activity in which the person is engaged and not on the surrounding temperature. Table 5-3 is used as the basis for the sensible and moisture gains from people at various activity levels. The number of occupants at each activity level at a given time is part of the information entered in the building use parameters in table 2-7. The sensible heat generated by the occupants of a zone at a particular time is then assumed to be described by the following equation [Building Environment, NBS (1977), p. A-21]:

$$Q_{\text{people},c} = (1 - r_p) \sum_{k=1}^{N_{\text{act}}} n_{p,k} W_{p,s,k} \quad (5-18)$$

where r_p : ratio of radiation energy to total sensible heat of people
 (=0.4)
 $n_{p,k}$: number of people who are doing the same (k-th) activity
 $W_{p,s,k}$: sensible heat generation by a person doing the k-th activity.
 N_{act} : number of activities

Table 5-3. Occupant sensible and moisture gains

[Table 18 entitled 'Rates of Heat Gain from Occupants of Conditioned Spaces' ASHRAE fundamentals (1981), p.26.25 and Threlkeld, page 363]

	sensible gain (Btu / hr.)	moisture gain (lb. water / hr.)
1. seated, very light work	230.	0.20
2. seated, light work (typing)	255.	0.27
3. standing, light work	315.	0.34
4. light bench work	345.	0.46
5. walking, 3 mph, light machine work	345.	0.74

5.4.5.2.2 Moisture Gain from People

$$M_{\text{people,lat}} = \sum_{k=1}^{N_{\text{act}}} n_{p,k} W_{p,\text{lat},k} \quad (5-19)$$

where N_{act} : number of activity
 $n_{p,k}$: number of people who are doing the same (k-th) activity
 $W_{p,\text{lat},k}$: moisture generation by a person doing the k-th activity

5.4.5.2.3 Convective Heat Gain from Equipment and Lighting

The total sensible internal gain from equipment and lighting is determined from the gains due to lighting added to the gain due to equipment. Parameters for the lighting power, lighting type, and equipment sensible gain at various times of the day are entered in the building use parameter file (see table 2-7, for example). For building equipment, the sensible internal gain is described by the following equation [ASHRAE (1981), pp. 26.26 - 26.29]:

$$Q_{\text{equip,c}} = (1 - r_e) W_{e,s} \quad (5-20)$$

where r_e : ratio of radiation energy to total equipment energy
 (=0.2 to 0.8)
 $W_{e,s}$: total sensible energy produced by equipment

The sensible internal gain from lighting is assumed to be described by the following equation:

$$Q_{\text{light,c}} = (1 - r_l) W_l \quad (5-21)$$

where W_l : total electric input
 r_l : ratio of radiation energy to total light energy
 = 0.8 for incandescent lights [Building Environment, NBS (1977), p. A-25]
 = 0.5 for fluorescent lights

5.4.5.2.4 Moisture Gain from Equipment

Moisture gain from equipment is specified in the parameters for the building use as shown in table 2-7. The equation for equipment moisture gain is: [ASHRAE (1981), p. 26.26 - 26.28]

$$M_{\text{equip,lat}} = W_{e,\text{lat}} \quad (5-22)$$

where $W_{e,\text{lat}}$ is the total moisture produced by equipment.

5.4.6 Thermal Mass of Zone Air and Furnishings (MASSTH)

The thermal mass which stores energy and dampens fluctuations in zone air temperature is contained in the air in the zone and the zone furnishings, such as desks, cabinets, and partitions. The shell parameter file, an example of which is given in table 2-8, contains the volume of the zone and the thermal capacity of the furnishings. The capacity of the zone air is given by:

$$C_{air} = C_{p,i} \rho_i V_i \quad (5-23)$$

where $C_{p,i}$: specific heat of moist zone air
 ρ_i : density of zone air
 V_i : volume of zone air (volume of interior space) (parameter, table 2-8)

The total thermal mass of the zone is then:

$$F_{cz} = C_{fur} + C_{air} \quad (5-24)$$

where C_{fur} : thermal mass of furnishings (parameter, table 2-8)

5.4.7 Moisture Gain/Loss due to Infiltration (INFILW)

Moisture gain/loss due to infiltration is assumed to equal a coefficient multiplied by the difference in humidity ratio between zone and outdoor air. The coefficient is determined from:

$$F_{Im} = \rho_{infl} V_i I_{air} \quad (5-25)$$

where ρ_{infl} : density of infiltrated air
 I_{air} : air exchange rate (see equation 5-15)
 V_i : volume of zone (parameter, table 2-8)

The air exchange rate is determined by the same equation as in section 5.4.2. The density of the infiltration air is determined by taking the average of the densities of the zone air and the outdoor air. This function is considered to be time-dependent.

5.4.8 Moisture Gain/Loss from Supply Air

The moisture added to or removed from the zone by the air handling unit is determined from the difference in the humidity ratios of return and supply air. The equation used is:

$$F_{sw} = W_{sa1} m_{sa1} + W_{sa2} m_{sa2} - W_{ra} m_{ra} \quad (5-26)$$

where: W_{sa1} : humidity ratio of supply air
 m_{sa1} : mass flow rate of supply air
 W_{sa2} : humidity ratio of hot deck supply air (optional)
 m_{sa2} : mass flow rate of hot deck supply air (optional)
 W_{ra} : humidity ratio of return air
 m_{ra} : mass flow rate of return air

This function is considered to be time-dependent.

5.4.9 Mass of Zone Air and Furnishings that can Absorb Moisture (MASSA)

The mass in the zone which stores moisture and dampens fluctuations in zone humidity ratio is contained in the air in the zone and the zone furnishings, such as curtains, paper, and wood furnishings. The shell parameter file, an example of which is given in table 2-8, contains the volume of the zone and a factor which is used to produce an effective air mass for moisture absorption by the combination of the air and the zone furnishings. This factor is difficult to measure since the moisture absorption properties of office materials are not only difficult to determine but depend on air flow and existing moisture content. This function is considered time-independent. The moisture absorbing capacity of the zone air and furnishings is described by the following equation:

$$F_{mz} = \rho_i V_i R_{mg} \quad (5-27)$$

where ρ_i : density of zone air
 V_i : volume of zone air (volume of interior space)
 R_{mg} : a factor used to produce the effective air mass for moisture absorption by the zone furnishings and air.

5.4.10 Overall Thermal Conductance between Wall and Outdoor Air (CNDCTO)

Heat transfer between the mass center of the wall and the outdoor air is a combination of conduction heat transfer within the wall and convection heat transfer from the wall outer surface to the outdoor air. The overall conductance is expressed by:

$$F_{co} = \frac{1}{\frac{1}{h_o} + \frac{L_{ow}}{k_{ow}}} A_w \quad (5-28)$$

where L_{ow} : thickness of wall between the mass center and the outer surface.
 k_{ow} : overall conductivity of the wall between the mass center and the outer surface.
 h_o : combined heat transfer coefficient (radiative + convective) for heat transfer between the outer wall surface and the outside air.
 A_w : surface area of the exterior wall.

The four parameters in this equation are obtained from the shell parameter file, exemplified by table 2-8. This is considered a time independent function.

5.4.11 Thermal Conductance between the Wall and Indoor Air (CNDCTI)

Heat transfer between the mass center of the wall and the inner surface of the wall is by conduction. The thermal conductance is expressed by:

$$F_{ci} = \frac{k_{iw}}{L_{iw}} A_w \quad (5-29)$$

where L_{iw} : thickness of wall between the mass center and the inner surface.
 k_{iw} : overall conductivity of the wall between the mass center and the inner surface.
 A_w : surface area of the exterior wall.

The three parameters in this equation are obtained from the shell parameter file, exemplified by table 2-8. This is considered a time independent function.

5.4.12 Thermal Capacitance of the Wall

The mass in the exterior wall which stores energy and dampens fluctuations in wall temperature is contained in the building materials of which the wall is constructed. The wall is divided into an inner and outer section by the mass center of the wall. The shell parameter file, an example of which is in table 2-8, contains the thickness, density, thermal conductivity and specific heat of the inner and outer wall sections. This function is considered time-independent. The thermal capacitance of the exterior wall is described by the following equation:

$$F_{cw} = (C_{p,ow} \rho_{ow} L_{ow} + C_{p,iw} \rho_{iw} L_{iw}) A_w \quad (5-30)$$

where $C_{p,ow}$, $C_{p,iw}$: average specific heat of outer and inner sections of wall.

ρ_{ow} , ρ_{iw} : average density of outer and inner sections of wall.

L_{ow} , L_{iw} : thickness of outer and inner sections of wall.

A_w : area of the exterior wall.

5.4.13 Radiative Heat Transfer Coefficient (WRADIA)

Radiative heat transfer between the inner surface of the exterior wall and the other surfaces in the zone is assumed to be equal to a radiative heat transfer coefficient multiplied by the difference in the mean radiant temperature of the zone and the wall surface temperature. For simplicity, this mode of heat transfer was not implemented in the abridged building emulator model program. Determination of this mode of heat transfer involves the determination of view angle factors of surfaces which enclose the zone. [Walton (1980), Sowell and Walton (1980)]. Using the view angle, the radiant heat transfer coefficient could then be determined [Walton (1980), p. 69]. However, it is necessary to know the emissivities and the surface temperatures of all zone surfaces, as well as the specific geometry. The abridged model effectively assumes that the radiative coefficient is small or the difference between the surface and mean radiant temperatures is negligible.

5.4.14 Solar Energy Entering the Zone Absorbed by Walls (WSOLAR)

If the zone contains a glass window, solar energy may enter the zone through the window and be absorbed by the walls and furnishings. For simplicity, this mode of heat transfer was not implemented in the abridged building emulator model program. Since the only zone wall which has inner surface temperature as a state variable is the exterior wall, and this is the wall which is assumed to have a glass window, no solar energy from the window would be absorbed by the exterior wall. Solar energy could be absorbed by the furnishings, however. The abridged model effectively assumes that the zone walls are without windows. The equation for solar energy absorption is included in this section for completeness. If it is assumed that solar irradiation is not absorbed by the glass window:

$$F_{ts} = \frac{A_g r_g S_c I}{A_w} \quad (5-31)$$

where A_g : glass window area

r_g : solar transmittance through glass [ASHRAE (1981), p. 27.38]

I : total solar radiation on the glass window

S_c : shading coefficient [ASHRAE (1981), p.27.38]

5.4.15 Thermal Conductance Through Glass to Outdoor Air (GCNDCT)

Heat transfer between the inner surface of the glass window and the outdoor air is a combination of conduction heat transfer within the glass and convection heat transfer from the glass outer surface to the outdoor air. This mode of heat transfer is not included in the abridged emulator model program since the abridged model assumes that there are no windows in the zone. The overall conductance equation is included for completeness and is expressed by:

$$F_{Ag} = \frac{1}{\frac{1}{h_o} + \frac{L_g}{k_g}} A_g \quad (5-32)$$

where L_g : thickness of glass.
 k_g : conductivity of the glass.
 h_o : combined heat transfer coefficient (radiative + convective) for heat transfer between the outer glass surface and the outside air.
 A_g : surface area of glass window.

5.4.16 Thermal Convection from Inner Glass Surface to Indoor Air (GCNVCT)

Heat transfer between the inner glass surface and the zone air is assumed to be equal to a convective heat transfer coefficient multiplied by the temperature difference between the inner glass surface and the zone air. The heat transfer coefficient must be supplied in the building shell parameter file. This mode of heat transfer is not included in the abridged version of the building emulator model program since the abridged model assumes that there are no windows in the zone.

5.4.17 Radiant Heat Transfer between Glass and Zone (GRADIA)

Radiative heat transfer between the inner surfaces of windows and the other surfaces in the zone is assumed to be equal to a radiative heat transfer coefficient multiplied by the difference in the mean radiant temperature of the zone and the glass surface temperature. Since there are assumed to be no windows in the zone, this mode of heat transfer was not implemented in the abridged building emulator model program. Determination of this heat transfer is equivalent to the process described in section 5.4.13.

5.4.18 Mean Radiation Temperature (MRT)

The mean radiant temperature is used to determine radiation heat transfer between the zone environment and wall or glass surfaces. The mean radiant temperature is a function of wall and glass surface temperatures, the radiant heat from people, the radiant heat from equipment, the properties of the

surfaces, and the geometry of surfaces [Walton (1983), p. 69]. Radiation heat transfer is not included in the abridged version of the emulator model program and the equation for mean radiant temperature is not included here.

5.5 Property Equations for Moist Air

The building emulator model program uses a number of functions to determine properties of moist air. The equations used are not presented in this report, but the names of the computer routines, the property determined, and a reference for the equations, is given in table 5-4.

5.6 Local Equipment Model

The local heating and cooling equipment is defined as the equipment located in or adjacent to the zone which is designed to directly heat or cool only that zone. The purpose of this equipment is to adjust the energy in the incoming air from the air handling unit to match the heating/cooling requirements of the zone. There are three different types of local equipment which may be present. These are: 1. energy consuming local equipment such as reheat coils, fan coils, heat pumps, perimeter radiation, or electric heaters; 2. air volume reduction controls to adjust the volume of supply air to match the zone requirements for VAV systems; and 3. air mixing controls to mix two air streams of different temperatures to match the zone requirements for multizone or dual-duct systems. Local equipment is usually under local control, which means that the controller for the equipment is located adjacent to the zone and the control sensor is located in the zone.

The subroutine LOCAL in the building emulator model program is used to simulate local equipment and determine energy usage required to maintain the zone air temperature as close to a local setpoint as possible. This subroutine is called by the ZONE subroutine for each zone model time step in the solution of the zone model equations.

Table 5-4 Moist air property routines

CPAIR	: specific heat of moist air as a function of humidity ratio [ASHRAE fundamentals 1981, page 5.3]
RHOAIR	: density of moist air as a function of humidity ratio and dry bulb temperature [ASHRAE fundamentals 1981, page 5.3]
ENTHAL	: enthalpy of moist air as a function of dry bulb temperature, humidity ratio, and atmospheric pressure [ASHRAE fundamentals 1981, page 5.4]
TEMP	: dry bulb temperature of moist air as a function of enthalpy, humidity ratio, and atmospheric pressure [ASHRAE fundamentals 1981, page 5.4]
DEWPT	: dew point temperature of moist air as a function of humidity ratio, and atmospheric pressure [ASHRAE fundamentals 1981, page 5.4, equation 40b]
HUMRAT	: Humidity ratio of moist air as a function of dry bulb temperature, relative humidity, and atmospheric pressure [ASHRAE fundamentals 1981, page 5.4]
RELHUM	: Relative humidity of moist air as a function of dry bulb temperature, humidity ratio, and atmospheric pressure [ASHRAE fundamentals 1981, page 5.4]
PWSAT	: Saturation pressure of water vapor as a function of absolute temperature [ASHRAE fundamentals 1981, page 5.2]
TDBSAT	: dry bulb temperature of saturated air as a function of the enthalpy of saturated air and the atmospheric pressure [ASHRAE fundamentals 1981, page 6.5, table 2]

The zone model will require a value for the energy being added to or removed from the zone due to the HVAC system. This energy, designated as q_{ent} , which enters or leaves the zone, consists of two parts, the energy removed or added by the air from the air handling unit, q_{air} , and the energy removed or added by local energy consuming equipment, q_{local} . The q_{local} energy may not be present on certain systems. q_{air} can be calculated by:

$$q_{air} = m_{sa1} h_{sa1} + m_{sa2} h_{sa2} - h_i m_{ra} \quad (5-33)$$

where m_{sa} are supply air mass flow rates (1 indicates the cold deck and 2 the optional hot deck for a dual deck system), h_{sa} are the supply air enthalpies,

m_{ra} is the return air mass flow rate, and h_i is the interior space enthalpy of the zone.

The actions that the local equipment model simulates are those of the local controller which will control the local equipment to maintain a zone air temperature at a setpoint. If the actual zone air temperature deviates from the setpoint, the local controller will attempt to return the temperature to the setpoint by increasing or decreasing the local equipment output. A simple proportional plus integral control (PI-control) model will be used. For this model, the adjustment the local controller attempts to make to q_{ent} is determined from:

$$dq_{ent} = K_p (e - e_0) + K_I (e \, dt) \quad (5-34)$$

where e , error = $T_{setpoint} - T_i$, e_0 is the previous value of the error, K_I is an integral gain factor, K_p is a proportional gain factor, and dt is the zone model time step. Once dq_{ent} is determined, the type of HVAC system determines how q_{air} and q_{local} are to be determined.

If the system is dual deck, it is assumed that there is no local conditioning equipment beyond the mixing box for the two deck air streams. Then:

$$dq_{air} = dq_{ent} \quad (5-35)$$

$$q_{air}(t+dt) = q_{air}(t) + dq_{air} \quad (5-36)$$

The total mass flow rate of air from the air handling unit is assumed to be constant at m_{sa} . The supply air enthalpy after mixing must then be:

$$h_{sa} = \frac{q_{air}}{m_{sa}} + h_i \quad (5-37)$$

Since the flow rates of the two decks must sum to equal the total mass flow rate, and the two deck air streams are assumed to mix ideally and have a known supply air temperature, humidity ratio, and enthalpy, the unknown mass flow rates for the decks can be solved for:

$$m_{sa2} = \frac{m_{sa} (h_{sa} - h_{sa1})}{h_{sa2} - h_{sa1}} \quad (5-38)$$

$$m_{sa1} = m_{sa} - m_{sa2} \quad (5-39)$$

$$\text{also: } W_{sa} = m_{sa1} W_{sa1} + m_{sa2} W_{sa2} \quad (5-40)$$

If the system is a single deck VAV, it is assumed that there is no local

conditioning equipment beyond the VAV box for modulating the supply air flow rate into the zone. This may not be true for some systems, for example VAV reheat systems. Then:

$$dq_{air} = dq_{ent} \quad (5-41)$$

$$q_{air}(t+dt) = q_{air}(t) + dq_{air} \quad (5-42)$$

The enthalpy of the air from the air handling unit is assumed to be constant at h_{sa} . The mass flow rate, m_{sa} , can be varied. The supply air flow rate for the new value of energy addition to the zone must then be:

$$m_{sa} = \frac{q_{air}}{h_{sa} - h_i} \quad (5-43)$$

The local zone VAV box will have a maximum and minimum air flow rating. If these limits are exceeded, the air flow rate will be constrained to the limits. If this is the case, the energy entering the room will have to be recalculated based on the limited mass flow rate.

If the system is single deck constant volume, it is likely to have local conditioning equipment. In this case:

$$dq_{local} = dq_{ent} \quad (5-44)$$

$$q_{local}(t+dt) = q_{local}(t) + dq_{local} \quad (5-45)$$

If q_{local} exceeds the local capacity, it will remain at the local capacity. If q_{local} becomes negative, this represents a need for local cooling. If the local equipment has no cooling capacity, such as a reheat coil, then q_{local} will be set to zero. If cooling capacity is present, then q_{local} can take on negative values up to the cooling capacity of the local equipment.

6. OCCUPANT COMFORT MODEL

6.1 Assumptions and Purpose of Comfort Model

The purpose of the occupant comfort model is to determine in a basic way if the conditions in the zone are in accordance with ASHRAE standard 55-74 for thermal comfort. This standard basically assumes that comfort is acceptable if the zone dry bulb temperature and humidity ratio are within certain limits.

The test for comfort is only performed if the building zone is determined to be in an occupied state. The zone is assumed to be occupied if the internal gain schedule table, contained in the model function SCHED, predicts that the sensible gain from people is non-zero for the current time-of-day. (see section 5.4.5).

6.2 Comfort Envelope Equations

The equations to determine if the current state of zone air is within the ASHRAE comfort limits are based on the simple two-dimensional geometry of the psychometric chart. The upper and lower comfort limits for humidity ratio are constant and this allows a simple comparison of zone humidity ratio to the limits. If the humidity ratio in the zone is greater than 0.012 or less than 0.0044 pounds of water per pound of dry air then the zone is automatically outside of comfort limits.

The maximum and minimum comfort limits for dry bulb temperature are a linear function of humidity ratio between the upper and lower humidity ratio limits as expressed by:

$$T_{\text{lower limit}} = 72.58 - 131.58 W_{za} \quad , \quad \text{and} \quad (6-1)$$

$$T_{\text{upper limit}} = 81.73 - 394.74 W_{za} \quad . \quad (6-2)$$

where W_{za} is the zone humidity ratio in pounds of water per pound of dry air, and T is the dry bulb temperature in degrees Fahrenheit. If the zone dry bulb temperature is above or below these limits, then the zone is outside of comfort limits.

The total time that the zone is outside of comfort limits during occupied hours is determined by the comfort model subroutine. The maximum and minimum values of zone dry bulb temperature and relative humidity are also recorded.

7. COMPILATION OF ENERGY USE

The predicted energy used by the emulated building during a test run of the emulator is determined by the FORTRAN subroutine CMPILE. CMPILE uses the values of the temperature, enthalpy, and air flow rate variables in the state vector to calculate the energy used between the current and previous time steps in several categories, and essentially integrates the energy use by keeping cumulative totals which are placed in the state vector.

7.1 Categories of Energy Use

Energy used by a building is assumed to be categorized as follows:

1. energy used by the fans in the air handling unit (the power used by the fans will be constant unless a variable air volume system is used, in which case fan power will vary as a function of air flow).
2. energy used to heat or cool the air passing through the air handling unit (this would not include cooling by outside air).
3. energy used by local space heating or cooling equipment (reheat coils, heat pumps, fan coils, perimeter radiation, air conditioners).

It is assumed that the calculated energy values are not in terms of any fuel and do not include any plant efficiencies. The energies are either in energy added to the air and extracted from steam or hot water for heating, or in energy required to be mechanically extracted from the air by chilled water or refrigerant for cooling.

There are 4 primary sources of reduction in energy use which EMCS algorithms may cause. Values for the energy reductions may be calculated from the above types of energy use in a building. These are:

1. savings from not running electrical loads (fans, pumps).
2. savings from reducing the daily heating or cooling requirements of a building by reduction of operating hours or changing of local space temperature setpoints.
3. savings by using the outside air for heating or cooling and avoiding mechanical heating or cooling.
4. savings from reduction of reheating or recooling of air passing through the air handler and building space for purposes of humidity control and compensation for load variation between zones. These causes of energy consumption are sometimes termed system effects, since the amount of energy for this purpose will vary between different HVAC systems, such as between reheat and multizone.

7.2 Equations for Energy Use

The first category of energy consumption is air handling unit fan energy consumption. If the system is constant volume, the steady-state power consumption of the fan can be used to calculate energy. If the system is variable air volume, it is assumed that the fan power consumption will vary with the volume flow rate through the unit. If the rated power consumption of a fan is known at a rated flow rate, then the power consumption at another flow rate can be determined based on fan law number 3 from the ASHRAE equipment handbook [1983, page 3.5, table 2]:

$$P_{fan} = P_{rated} \left(V_a / V_{rated} \right)^3 \quad (7-1)$$

where: P_{rated} : power consumption of fan at rated air flow rate.
 V_{rated} : rated fan volumetric air flow rate.
 V_a : current volumetric flow rate.

The fan energy between the current and last time step is determined by multiplying P_{fan} by the emulator model time step. The cumulative energy for the fan is determined by adding the current time step energy to the sum of values of energy for previous time steps.

The thermal energy used for heating and cooling the building should be divided into the energy added to the building air for heating purposes and the energy removed from the building air for cooling purposes. Therefore the energy values will always have two parts, heating and cooling. The summation or subtraction of two energies will then consist of the separate summation or subtraction of the heating and cooling parts (this is analogous to two-dimensional vectors with x and y components). For the following equations, an energy rate is calculated. This rate is multiplied by the emulator model time step to determine the energy used since the last time step. The cumulative energy is obtained by adding this to the sum of energy values of previous time steps.

The requirements energy is the energy required to bring the air leaving the building zones through the return ducts and the ventilation air to the level of the supply air enthalpy (including both air streams if dual deck).

The requirements energy rate (power) is:

$$q_{req} = m_{sal} (h_{sal} - h_{mc}) \quad (7-2)$$

where the mc subscript indicates the mixed air temperature in the air handling unit with only minimum outside air or ventilation air (see section 4.2). If $q_{req} < 0$ this is cooling energy, if $q_{req} > 0$ this is heating energy. If the system is dual deck there is an additional component of the requirements energy rate for the hot deck.

$$q_{req2} = m_{sa2} (h_{sa2} - h_{mc}) \quad (7-3)$$

If $q_{req2} < 0$ this is cooling energy, if $q_{req2} > 0$ this is heating energy. The hot deck component is added to the cold deck component of requirements energy, keeping heating and cooling energies separated.

The actual energy is the energy required to bring the air passing through the air handler to the level of the supply air enthalpy from the level of the mixed air enthalpy. This is usually equal to the energy supplied or removed by the heating and cooling coils. This actual energy will be less than the requirements energy since part of the requirements energy can be met by an economizer algorithm using outdoor air for cooling.

The actual energy rate (q_{act1} for single or cold deck and q_{act2} for hot deck if a dual deck system) is then:

$$q_{act1} = m_{sal} (h_{sal} - h_{ma}) \quad (7-4)$$

$$q_{act2} = m_{sa2} (h_{sa2} - h_{ma}) \quad (7-5)$$

q_{act1} and q_{act2} are summed, keeping heating and cooling energies separated.

The requirements and actual energy can be used to determine the economizer energy. This is not usually considered an energy use, since the outdoor air costs nothing to condition. However, for purposes of calculating energy savings for economizer algorithms (savings category 3 above) it is useful to consider this as energy consumption. The economizer energy rate is:

$$q_{econ} = q_{req} - q_{act} \quad (7-6)$$

The actual energy can be divided into two parts which are the other two categories of building energy use. The energy that would be required to bring the mixed air to the actual condition of the air entering the building space (after mixing for a dual deck system) can be termed the load energy. This will equal the actual energy for all systems except dual deck. This represents the energy requirements with system effects minimized (used for savings in category 2, above). The load energy is:

$$q_{load} = (m_{sal} h_{sal} + m_{sa2} h_{sa2}) - (m_{sal} + m_{sa2}) h_{ma} \quad (7-7)$$

The final category of energy use is the energy used for reheating and recooling of air (used for savings in category 4, above). This is defined as:

$$q_{rhc} = q_{act} - q_{load} + q_{local} \quad (7-8)$$

This sum is of the heating and cooling components of the energies.

When a test run using the emulator is complete, the emulator model program will generate a summary report file containing energy usage for the emulated building over the test period. This task is performed by subroutine REPORT. The report will contain energy usage in the categories discussed above for heating and cooling energy components. An example energy report is given in table 7-1. The report file will also contain results on the amount of time the zone was not within comfort limits and the maximum and minimum space temperatures and relative humidities reached during occupied hours.

FAN ENERGY		
	HEATING	COOLING
ECONOMIZER ENERGY		
LOAD ENERGY		
REHEAT/RECOOL ENERGY		

8. SUMMARY

The use of a building emulator is one of the approaches to testing of EMCS systems without making actual connections to HVAC equipment or a building. The NCEL/NBS emulator will be used for either factory or field acceptance tests of EMCS algorithms. The building simulation program in the emulator is the main part of this report. This program simulates the responses of a building to EMCS control actions.

The building emulator program was written in FORTRAN 77 and the source code is appended in the APPENDIX. State variables in the emulator model are analog sensor, energy, command, and comfort variables. The building emulator model program contains the weather (WEATHR), air handling unit (AHU), zone (ZONE), and comfort (COMFRT) model. The use of energy during a simulation is accumulated by the energy compilation subroutine (COMPILE). This energy use information is useful to evaluate the performance of an EMCS algorithm.

Prior to simulation, data files of initial values of state variables, building shell parameters, HVAC system parameters, and weather data parameters must be called. The air handling unit model is a steady-state model, while the zone model is a dynamic model. In the zone model, a system of first order ordinary differential equations is solved by the explicit forward difference scheme. The time step for the difference scheme is adjusted according to the changes of state variables. By using this adaptive time step, which is uniformly distributed in a given emulator simulation time period, savings in computation time can be realized when the state variables approach steady state.

The air handling unit model simulates a single deck (or single duct), constant volume system without humidity control as shown in Figure 4-2. Damper positions of the air handling unit are varied if economizer option is selected. A single zone with exterior walls without window is modeled under the assumptions described previously. For this abridged system, a local equipment model is implemented. Heating/cooling energy delivered from the local equipment to zone air is adjusted under the control law of the proportional plus integral controller (PI-controller). Capabilities of simplified current models can be upgraded by providing necessary information in the spaces already reserved for future extension.

COMPUTER PROGRAM LISTINGS

```

1 C Version 1.7 - FEBRUARY 05, 1985 - W.B. MAY ,NATIONAL BUREAU OF STANDARDS
2 C=====
3 PROGRAM ALGTST
4 C=====
5 C This is the main program used to develop and test simulation routines
6 C for a simple building model to be used in an EMCS algorithm tester
7 C developed by the U.S. Navy Civil Engineering Laboratory. This test
8 C program takes the place of the EMCS tester software. Subroutine
9 C EMODEL is the emulator model. Subroutine UPDATE represents the I/O
10 C task which determines if any commands have arrived from the EMCS and
11 C updates the analog and digital signals to the EMCS based on the
12 C simulation calculations. It is assumed that these routines will
13 C eventually run in parallel, UPDATE at a higher frequency. Parallel
14 C execution is approximated by serial calls, but with UPDATE being
15 C called more often.
16 C
17 C Determine start time
18 CALL SYNCCL
19 C-----
20 C Update commands and outputs
21 C
22 1000 CALL UPDATE
23 C-----
24 C Call the emulator model
25 C
26 CALL EMODEL
27 C-----
28 C Update clock
29 C
30 CALL ECLOCK
31 GO TO 1000
32 END
33 C=====
34 BLOCK DATA COMDAT
35 C=====
36 C This module contains a list of all common block data and globals which
37 C are referenced in the support routines for the EMODEL subroutine.
38 C Additional common blocks used only with EMODEL are described in the
39 C subroutine EMODEL or the subroutine PARAMA.
40 C common blocks are:
41 C ASENSR - contains all analog sensor readings in arrays. Sensor
42 C readings are copied from the emulator model outputs after
43 C each time step. Array index indicates which of 5 possible
44 C buildings the reading is from.
45 C COMMND - contains all command digital inputs from the EMCS in arrays.
46 C readings are directly available to the emulator model.
47 C CPA - contains all control point adjustments from the EMCS in arrays.
48 C DSENSR - contains all digital sensor readings in arrays.
49 C EVENT - GLOBAL which is a logical variable indicating an EMCS command.
50 C PAST - contains day, hour, minute, and second that model subroutine
51 C PFILES - contains the names of all parameter files, and the season.
52 C was last called, and the simulation major timestep.
53 C STATE1 - contains the state variables for the emulator model.
54 C TIME - current time is broken into DAY, HOUR, MINUTE, SECOND. In this
55 C test program, all times are zero at the start of the program.
56 C the basic time step of the program is one second. ENDDAY,ENDHR,
57 C ENDMIN, and ENDSEC are the scheduled time to end the simulation.

```

```

58 C UNITS - contains the logical units used by the program for various
59 C inputs and outputs.
60 C-----
61 C
62 C TOUTA - EMCS analog input, Temperature, Outside Air (F)
63 C RHOUTA - EMCS analog input, Relative Humidity, Outside Air (%)
64 C TZONEA - EMCS analog input, Temperature, Space (F)
65 C RHZONEA - EMCS analog input, Relative Humidity, Space (%)
66 C TRETA - EMCS analog input, Temperature, Return Air (F)
67 C RHRETA - EMCS analog input, Relative Humidity, Return Air (%)
68 C ZHCDEM - EMCS analog input, Position, Reheat Valve (Btu/s)
69 C TSUPA - EMCS analog input, Temperature, Supply Air (F)
70 C TMIXA - EMCS analog input, Temperature, Mixed Air (F)
71 C
72 C REAL TOUTA,RHOUTA,TZONEA, RHZONEA, TRETA,
73 C & RHRETA, ZHCDEM, TSUPA, TMIXA
74 C COMMON / ASENSR / TOUTA,RHOUTA,TZONEA(5),RHZONEA(5),TRETA(5),
75 C & RHRETA(5),ZHCDEM(5),TSUPA(5),TMIXA(5)
76 C DATA TOUTA,RHOUTA,TZONEA,RHZONEA,TRETA,RHRETA,ZHCDEM/27*0.0/
77 C DATA TSUPA,TMIXA/10*0.0/
78 C
79 C ON - EMCS command, Supply Fan On/Off
80 C ECON - EMCS command, O.A. Damper Off/Auto
81 C VENT - EMCS command, Ventilation Damper Open/Close
82 C SETBAK - EMCS command, Zone Thermostat Setback On/Off
83 C
84 C LOGICAL ON, ECON, VENT, SETBAK
85 C COMMON / COMMND / ON(5),ECON(5),VENT(5),SETBAK(5)
86 C DATA ON,ECON,VENT,SETBAK/20*.FALSE./
87 C
88 C SUPPLY - EMCS CPA, Supply Air Temperature (F)
89 C ZONE - EMCS CPA, Zone Temperature (F)
90 C
91 C REAL SUPPLY, ZONE
92 C COMMON / CPA / SUPPLY(5),ZONE(5)
93 C DATA SUPPLY,ZONE/10*0.0/
94 C
95 C DPSSF - EMCS digital input, differential Pressure Switch, Supply Fan
96 C
97 C LOGICAL DPSSF
98 C COMMON / DSENSR / DPSSF(5)
99 C DATA DPSSF/5*.FALSE./
100 C
101 C EVENT - Logical variable which is true when a command from the EMCS
102 C file has been received.
103 C
104 C LOGICAL EVENT
105 C GLOBAL EVENT
106 C
107 C GLDDAY - Day number when EMODEL subroutine was last called.
108 C GLDHR - Hour of day when EMODEL subroutine was last called.
109 C GLDMIN - Minute of hour when EMODEL subroutine was last called.
110 C GLDSEC - Second of minute when EMODEL subroutine was last called.
111 C STEP - Major time step for simulation. model routines for AHU,
112 C weather, zone, comfort, and energy compilation are called
113 C at this interval. Not the same as the Euler timestep used
114 C within the zone model.
115 C

```

```

116      INTEGER      OLDDAY,OLDHR,OLDMIN,OLDSEC,STEP
117      COMMON / PAST / OLDDAY,OLDHR,OLDMIN,OLDSEC,STEP
118      DATA OLDDAY,OLDHR,OLDMIN,OLDSEC,STEP/4*0,30/
119
120      C
121      C HVFILE - Character filename of HVAC equipment parameter file.
122      C USFILE - Character filename of Building usage parameter file.
123      C CLFILE - Character filename of climate description parameter file.
124      C SHFILE - Character filename of building shell parameter file.
125      C INFILE - Character filename of state vector initialization file.
126      C SEASON - Character name of weather season to use in test.
127
128      CHARACTER*15      HVFILE,USFILE,CLFILE,SHFILE,INFILE,SEASON
129      COMMON / PFILES / HVFILE,USFILE,CLFILE,SHFILE,INFILE,SEASON
130
131      C
132      C A      - Real array containing state variables at the current time.
133      C L      - Logical array containing current logical state variables.
134
135      LOGICAL      L
136      REAL      A
137      COMMON / STATE1 / A(100),L(100)
138      DATA A/100*0.0/,L/100*.FALSE./
139
140      C
141      C DAY      - Current day number, first day of test is day 1.
142      C HOUR      - Current hour of day, from 0 - 23.
143      C MINUTE      - Current minute within the hour, 0 - 59.
144      C SECOND      - Current second within the minute, 0 - 59.
145      C ENDDAY      - Day number on which the test is to stop.
146      C ENDHR      - Hour of the day on ENDDAY within which test is to stop.
147      C ENDMIN      - Minute within ENDHR within which test is to stop.
148      C ENDSEC      - Second within ENDMIN within which test is to stop.
149
150      C
151      INTEGER      DAY,HOUR,MINUTE,SECOND,ENDDAY,ENDHR,ENDMIN,ENDSEC
152      COMMON / TIME / DAY,HOUR,MINUTE,SECOND,ENDDAY,ENDHR,ENDMIN,ENDSEC
153
154      C
155      C CLU      - Logical Unit for writes to console.
156      C FLU      - Logical Unit for read from EMCS command input file.
157      C ILU      - Logical Unit for read from console.
158      C PLU      - Logical Unit for read from parameter files.
159
160      C
161      INTEGER      CLU,FLU,ILU,PLU

440     SUBROUTINE SBTIME(DAY, HOUR, MIN, SEC, MDAY, MHOUR, MMIN, MSEC, DSEC)
441 C=====
442 C This module subtracts two sets of time integers (xxx - Mxxx) and
443 C puts the result in seconds into DSEC.
444 C
445 C Input variables:
446 C DAY - Day number of first time from which second time is subtracted.
447 C HOUR - Hour of first time.
448 C MIN - Minute of first time.
449 C SEC - Second of first time.
450 C MDAY - Day number of second time which is to be subtracted from first.
451 C MHOUR - Hour of second time.
452 C MMIN - Minute of second time.
453 C MSEC - Second of second time.
454 C
455 C Output variables:
456 C DSEC - differential in seconds between first and second times.
457 C
458     INTEGER DAY, HOUR, MIN, SEC, MDAY, MHOUR, MMIN, MSEC, DSEC

941 C
942 C Local Variables:
943 C AINIT - Temporary value to hold state vector initializer read from
944 C          initialization file.
945 C BTUSPW - Conversion factor, Btu per Watt.
946 C BULB - Indicates type of lighting in describing building schedule.
947 C CHMAX - Time of maximum outdoor dry bulb temperature, hrs from midnight.
948 C CTMAX - Maximum daily outdoor temperature for a particular season in F.
949 C CTMIN - Minimum daily outdoor temperature for a particular season in F.
950 C EQUIPL - Equipment moisture gain for a schedule period in lb water/hr.
951 C EQUIPS - Electric power used by any equipment in zone for a schedule period
952 C          in Watts.
953 C INDEX - Temporary value to hold state vector index read from initialization
954 C          file.
955 C LIGHT - Lighting power in the zone for a schedule period in watts.
956 C LINIT - Temporary variable to hold logical state vector initializer read
957 C          from initialization file.
958 C NACCAT - Number of possible activity categories for occupants of zone.
959 C NACTIV - Array containing number of occupants in NACCAT activity categories
960 C          for a schedule period.
961 C OCCLAT - Occupant moisture gain per person for a schedule period in
962 C          lb water/hour.
963 C OCCSEN - Occupant sensible heat gain per person for a schedule period in
964 C          Btu/hr.
965 C RE - ratio of radiated energy to total equipment energy for a schedule
966 C          period.
967 C RL - ratio of radiated energy to total lighting energy for a given
968 C          lighting type.
969 C RP - ratio of radiated energy to total sensible heat of people.
970 C SEASIN - temporary variable to hold season name from climate file for
971 C          comparison with desired season in variable SEASON.
972 C TOLAT - total moisture gain from occupants for a schedule period in lb.
973 C          water/hour.

1601     INTEGER        DAY,HOUR,MINUTE,SECOND,ENDDAY,ENDHR,ENDMIN,ENDSEC
1602     COMMON / TIME / DAY,HOUR,MINUTE,SECOND,ENDDAY,ENDHR,ENDMIN,ENDSEC
1603 C
1604 C Local Variables:
1605 C
1606 C ADSTEP - Logical variable which if true, enables the use of the algorithm
1607 C          to internally determine a minimum Euler timestep. If false, a
1608 C          fixed Euler timestep is used.
1609 C DELMAX - The maximum change in state variable allowed for any of the
1610 C          differential equations describing the zone within one Euler
1611 C          timestep in degrees F. Theoretically, each differential equation
1612 C          should have its own DELMAX. A simplification of this is used.
1613 C EISMIN - Minimum Euler timestep which can be used.
1614 C EISTEP - Current Euler timestep to be used in solving the differential
1615 C          equations. determined from  $dt = dY_{max} / (dY/dt)$ , where  $dY_{max}$  is
1616 C          DELMAX.
1617 C EUSTEP - Euler timestep to be used if ADSTEP is false.
1618 C FMAX - Magnitude of the largest  $dY/dt$  for all of the first order
1619 C        differential equations used to describe
1620 C        the zone.
1621 C ITIME - A time value which is a combination of the current minutes and
1622 C          seconds of the time of day. Used to determine if time-dependent
1623 C          functions should be recalculated.

```

```

1624 C NDEQNS - Number of variables in the zone model state vector which are
1625 C         defined by differential equations. These variables will be the
1626 C         first NDEQNS variables in the vector. The remaining variables
1627 C         will be defined by algebraic equations.
1628 C         in the state vector
1629 C NITER - Number of iterations required to solve the zone differential
1630 C         equations for one major simulation timestep.
1631 C NSTVAR - Total number of variables in the zone model state vector.
1632 C STEP - Floating point equivalent of the integer major timestep in the
1633 C         simulation.
1634 C Y - Zone model state vector which is a subset of the simulation
1635 C         state vector. Elements are defined as:
1636 C         Y(1): zone dry bulb temperature (F)
1637 C         Y(2): zone humidity ratio
1638 C         Y(3): zone internal wall temperature at mass center (F)
1639 C         Y(4): zone interior wall temperature (F)
1640 C         Y(5): zone interior glass temperature (F)

1690 C=====
1691 C This subroutine advances the system of NDEQNS ODE'S described by:
1692 C  $dy(i)/dt = FNC(i,t,Y(1),Y(2),\dots,Y(NDEQNS))$  by one step of size
1693 C TIMEST using the explicit Euler method. Y contains the dependent
1694 C variables and is overwritten with the new values.
1695 C
1696 C Input variables:
1697 C NDEQNS - Number of differential equations to be advanced.
1698 C TIME - A time value which must be distinct from the time value on
1699 C the previous call to EULER.
1700 C Y - contains the current values of the dependent variables.
1701 C TIMEST - The Euler timestep size.
1702 C FNC - The address of the function describing  $dy/dt$ .
1703 C NSTVAR - dimension of the Y array. Not all elements may be advanced.
1704 C
1705 REAL Y(NSTVAR),TIMEST
1706 INTEGER TIME
1707 C
1708 C Output variables: none
1709 C Y - contains the new value of the dependent variables.

10. SUPPLEMENTARY NOTES <input type="checkbox"/> Document describes a computer program; SF-185, FIPS Software Summary, is attached.						
11. ABSTRACT (A 200-word or less factual summary of most significant information. If document includes a significant bibliography or literature survey, mention it here) A building emulator can be used to test energy management and control systems (EMCS). The emulator uses a computer program to simulate the responses of a building including the equipment, building space, and building envelope to EMCS commands. Building model software for the emulator has been developed at the National Bureau of Standards (NBS) in an effort to assist the United States Naval Civil Engineering Laboratory (NCEL), which is developing a sophisticated building emulator. The concept of the building emulator and the building emulator computer program are described in this report. The program includes the weather, the air handling unit, the zone, and the comfort model. In addition, the energy compilation routine is also included. The models presented here are simplified models. With these abridged models, a single zone building with exterior walls and a single deck air handling unit are simulated. A complete FORTRAN source code of the building emulator computer program is appended.						
12. KEY WORDS (Six to twelve entries; alphabetical order; capitalize only proper names; and separate key words by semicolons) air handling unit simulation model; building emulator; building space zone model; computer simulation; EMCS algorithms; energy management and control systems (EMCS); HVAC emulator; local equipment simulation model; testing EMCS algorithms.						
13. AVAILABILITY <input checked="" type="checkbox"/> Unlimited <input type="checkbox"/> For Official Distribution. Do Not Release to NTIS <input type="checkbox"/> Order From Superintendent of Documents, U.S. Government Printing Office, Washington, D.C. 20402. <input checked="" type="checkbox"/> Order From National Technical Information Service (NTIS), Springfield, VA. 22161			14. NO. OF PRINTED PAGES 132 15. Price \$16.95
